FINAL M.B., CH.B.—*Parts II and III*: J. Edwards, with second-class honours, Aileen K. Adams, H. Debovitch, C. Gething, A. P. Hayhurst, R. Horn, J. F. Hudson, G. M. King, J. Mackinnon, J. B. Maxfield, Cora H. M. Middleton, Monica H. Roper, Margaret M. P. Ryan, Joan Simon.

SOCIETY OF APOTHECARIES OF LONDON

Diploma in Industrial Health

In view of the importance attached to the study of the health of the worker in relation to both occupation and working environment in their widest sense, and the development of this study as a special branch of medicine, the Society has decided to institute a Diploma in Industrial Health. The examination for this diploma will be open to all registered medical practitioners who have (*a*) been engaged in the practice of industrial medicine in a whole-time capacity for a period of not less than two years, or (*b*) been engaged in the practice of industrial medicine in a part-time capacity for a period of not less than four years.

The Society understands that courses in the subject are to be held in the future, and, subject to their fulfilling the requirements laid down in the Society's regulations, these will be recognized as qualifying for admission to the examination. Candidates who produce evidence of having completed the course, and who have the requisite experience in the practice of industrial medicine, will be eligible. The syllabus and regulations covering the examination will shortly be obtainable from the Registrar, Society of Apothecaries, Black Friars Lane, Queen Victoria Street, E.C.4.

ROYAL COLLEGE OF PHYSICIANS OF LONDON

Dr. W. Russell Brain, F.R.C.P., will deliver the Bradshaw Lecture at the College (Pall Mall East, S.W.) on Thursday, Nov. 8, at 5 p.m. His subject is "Speech and Handedness."

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* notifications of scarlet fever rose during the week by 230, those of diphtheria by 72, and of acute pneumonia by 58.

The greatest increases over last week's figures in scarlet fever notifications were 47 in Lancashire, and 39 in Yorks West Riding. The largest local outbreak of diphtheria was that of Worcestershire, Martley R.D. 12, and the other large local rises were 18 in Northumberland (due to a general rise throughout the county), and 53 in Yorks West Riding (mainly contributed by the county boroughs). Although the total notifications of whooping-cough fell by only 18, there were several fairly large variations in the trends for the counties, the largest being decreases of 47 in Lancashire and 36 in Essex, and a rise of 25 in Staffordshire. Lancashire reported 34 more cases of pneumonia than last week.

The largest returns for dysentery were London 57 (St. Pancras 14), Surrey 47 (Banstead U.D. 13, Coulsdon and Purley U.D. 10), Lancashire 40 (Liverpool C.B. 18, Manchester C.B. 11), Warwickshire 38 (Birmingham C.B. 16, Warwick R.D. 17), Glamorganshire 21 (Cardiff C.B. 18), Essex 14.

In *Scotland* scarlet fever notifications were 33 higher than last week, and those for acute pneumonia were 32 higher; notifications of dysentery and diphtheria rose by 9 and 6 respectively. The largest local increase in diphtheria was one of 10 in the city of Dundee. The chief centres of dysentery were Glasgow 50, and Edinburgh 22.

In *Eire* notifications of diphtheria were 35 higher, and of diarrhoea and enteritis 50 higher, than last week. Cases of the latter disease rose from 80 to 114 in Dublin C.B.

In *Northern Ireland* scarlet fever notifications rose by 7, while those for diphtheria fell by 8.

Quarterly Returns for Eire

During the June quarter the birth rate was 24.0 per 1,000, and was 0.4 above that for the corresponding quarter of the previous year. Infant mortality was only 59 per 1,000 births, being 11 and 18 below the rates for the two preceding second quarters. Deaths under the age of 2 attributed to diarrhoea and enteritis were 204, including 97 in the city of Dublin. The general death rate was 14.4 per 1,000, being 0.7 below the June quarter of 1944. The death rate per 1,000 from pulmonary tuberculosis was 1.1, and for other forms 0.4; the rates for the corresponding quarter of last year were 1.2 and 0.4. Diphtheria was the cause of 55 deaths, and whooping-cough of 48.

Week Ending September 22

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,361, whooping-cough 1,903, diphtheria 496, measles 397, acute pneumonia 347, cerebrospinal fever 39, acute poliomyelitis 45, dysentery 270, paratyphoid 8, typhoid 11.

Quarantine for Scarlet Fever in New York

The Board of Health of the City of New York decided in December, 1944, to include scarlet fever in the larger classification of "streptococcal sore throat, including scarlet fever," and recommended isolation of such cases to the duration of the acute stage, the *minimum* period being seven days. The application of restrictive measures to scarlet fever and not to other streptococcal throat infections has always been a weakness of public health regulations which called for revision. Considerable argument can be advanced, too, for a short isolation period. Scarlet fever patients are usually clinically recovered within 10 to 14 days. Does isolation beyond that point decrease the risk of infectivity? Most fever hospital clinicians would agree that it does not. Indeed, under open scarlet fever ward conditions the reverse is probably true.

No. 37

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Sept. 15.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

---

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to movements of population, birth and death rates for Northern Ireland are still not available.

Medical News

The annual general meeting of the Research Defence Society will be held at 26, Portland Place, W., on Friday, Oct. 12, at 3.15 p.m., when the fourteenth Stephen Paget Memorial Lecture will be delivered by Sir William Savage. His subject is: "Public Health and its Debt to Experimental Medical Research."

The inaugural address of the 209th session of the Royal Medical Society of Edinburgh will be given by Dr. Charles Hill, Secretary of the British Medical Association, at 7, Melbourne Place, Edinburgh, on Friday, Oct. 12, at 8 p.m. His subject is "The Future of Medical Practice."

The inaugural lecture of the Faculty of Medicine of the University of Leeds will be given by Dr. Raymond Priestley, *M.C.*, M.A., D.Sc., Principal and Vice-Chancellor of the University of Birmingham, in the Riley-Smith Hall of the University Union on Monday, Oct. 15, at 3 p.m. His subject is "Scott's Northern Party: A Study of Survival in the Antarctic." Members of the medical profession are cordially invited to be present.

A meeting of the Society for the Study of Inebriety will be held at the Medical Society of London (11, Chandos Street, W.) on Tuesday, Oct. 16, at 4 p.m., when Sir Adolphe Abrahams will read a paper entitled "A Layman Looks at Alcohol." A discussion will follow.

A members' meeting of the Eugenics Society will be held at the Rooms of the Royal Society (Burlington House, Piccadilly, W.) on Tuesday, Oct. 16, at 5.30 p.m., when Dr. W. Mayer-Gross will speak on "Mental Health Problems in a Rural Area." All interested are invited to attend.

A series of lectures will be given at the Royal Institute of Public Health and Hygiene (28, Portland Place, W.) on Wednesdays at 3.30 p.m., as follows: Oct. 17, Mr. F. D. Saner, "Cancer of the Breast—Its Diagnosis and Treatment"; Oct. 24, Dr. Doyne Bell, "Some Aspects of the Public Responsibility for Child Health"; Oct. 31, Major Joseph Minton, R.A.M.C., "Eye Diseases in the East"; Nov. 7, Mr. R P. Osborne, "Modern Methods in the Treatment of Burns"; Nov. 14, Mr. Anthony Green, "Uses of Radiology in Medicine"; Nov. 21, Mr. J. C. Ainsworth-Davis, "Urology: Some Common Symptoms and their Significance"; Nov. 28, Dr. W. W. Payne, "Diabetes in Childhood."

The annual general meeting of the Scottish Group of the Association of Industrial Medical Officers will be held at the Institute of Hygiene, University of Glasgow, on Wednesday, Oct. 17, at 3.15 p.m.

Mr. Aneurin Bevan, Minister of Health, has appointed Lord Rushcliffe to be chairman of the Advisory Committee on the Welfare of the Blind in succession to Lord Blanesburgh, who has resigned on account of ill-health.

The Minister of Supply has made an Order revoking the Control of Pyrethrum (Nos. 1 and 2) Orders, which prohibited the acquisition, disposal, treatment, use, and consumption of pyrethrum and pyrethrum products except under licence. The Ministry of Supply holds stocks of pyrethrum flowers which were acquired for war purposes and are now available to meet civilian requirements.

The Minister of Health, after investigation by officials on the spot, has found no grounds for the allegation that there has been gross maladministration at Moor Park Hospital, North Shields, Northumberland, or negligence by the medical and nursing staffs. These findings follow an inquiry into complaints contained in a diary of a former patient. The report of the Minister says, however, that, disregarding the complaints of an individual patient, it appeared that the general condition of the premises used for tuberculosis treatment left much to be desired. He was aware that the Tynemouth Council contemplated replacement but was prevented by the war from proceeding with a new sanatorium. The Council at its meeting on Sept. 26 agreed to take steps to obtain a prefabricated building to accommodate 40 to 50 patients, and to proceed with the scheme for permanent buildings.

An exhibition of the peacetime uses of "perspex" will be held at the regional office of Imperial Chemical Industries Ltd., at the Chamber of Commerce, 95, New Street, Birmingham, from Oct. 8 to 13, from 10 a.m. to 6 p.m. daily. The various sections include one showing medical applications of "perspex."

Mr. F. Le Gros Clark, M.A., secretary of the Children's Nutrition Council, will speak on "World Famine this Winter? Analysis of the World's Food Situation" at a meeting arranged by the Socialist Medical Association, to be held on Friday, Oct. 12, at 7.30 p.m., at Friends House, Euston Road, London, N.W.

The following members of the medical profession have been released from internment in Japanese hands: Dr. Ralph Stockman Begbie, Dr. George Ian Hector Braine, Dr. Edward Wilfrid Kirk, Dr. Robert Michael Ballantyne Lowis, Dr. John Norrie McArthur, Dr. Margaret Henderson Thomson, M.B.E., and Dr. Cicely Delphine Williams.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Aitiology Westcent, London.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London.*

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Westcent, London.*

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Pamaquin in Benign Tertian Malaria

Q.—*It is stated frequently that in the treatment of malaria pamaquin reduces the number of relapses. Since the only specific advantage of pamaquin is that it destroys the sexual forms of the malignant tertian parasite (which presumably play no part in relapses), how is this action accounted for?*

A.—It is true that pamaquin has a selective action on the sexual forms of the malignant tertian parasite, but it has in addition some action on other forms. There is evidence that in the treatment of relapses in patients suffering from benign tertian malaria a combination of quinine and pamaquin has much more effect than quinine alone. The treatment consists of giving 10 grains of quinine and 0.01 g. of pamaquin three times a day; these doses are given for 10 days. This treatment appears to be much more effective than treatment with mepacrine, but it should be emphasized that it applies to patients having relapses from benign tertian.

Lumbar Puncture in Infants

Q.—*What are the special anatomical relations in the spinal column of a young infant which must be borne in mind when doing a lumbar puncture on the very young? Does the procedure differ from that in the adult?*

A.—The position of choice for puncturing the spinal membranes is the same at any age: that is to say, between the fourth and fifth lumbar vertebrae. The anatomical differences from the adult in a small baby are two: first, that the spinal canal is proportionately closer to the surface than in the adult, owing to the comparative shortness of the spinous processes; secondly, that the bones are much softer—in fact, almost entirely cartilaginous for the first few months. The consequence is that it is possible to miss tapping the fluid owing to pushing the needle right through the minute spinal canal. In a strong and resistant infant it is usually worth while to give a light anaesthetic in order to stop the sudden movements which will otherwise inevitably hamper a delicate process. As in adults, the spinal needle should never be thrust through the skin owing to the danger of punching out a piece and infecting the meninges with it. The skin should always be incised with a small sharp knife.

Varicose Ulcers

Q.—*A woman aged 71 has suffered from varicose veins for 35 years, accentuated after the birth of a son (primipara) at the age of 39. She wore elastic stockings and occasionally bandages up till 1929, when venous injections enabled her to do without artificial supports. Eight years ago there was a return of varicosity, and she has had to resume elastic stockings. Three months ago a small ulcer, which does not respond to local treatment, appeared on the right internal malleolus.*

A.—The patient seems to have had great benefit from injections 8 years ago, so that concentrating on the local treatment of the ulcer without attacking the fundamental cause seems to be the present mistake. The combination of ligature of the main trunks and injections will close the veins, and the ulcer will heal with no local applications at all.

Liver Extracts

Q.—*Which liver extract would most likely benefit cases of aplastic anaemia or essential thrombocytopenia? I am told the crudest is the best. What doses and for how long continued would constitute "intensive liver treatment"?*

A.—There is no evidence that any liver extract benefits aplastic anaemia or essential thrombocytopenia. Both diseases are characterized by a tendency to spontaneous remissions, and any apparent improvement under treatment with liver extract can be attributed to this phenomenon. Nevertheless, it is a good rule that no patient with a blood disease should be denied the opportunity of responding to liver therapy, though the ordinary dosage for pernicious anaemia should be sufficient for this purpose—i.e., 4 c.cm. of any reliable intramuscular extract twice weekly for a month.

Liver extracts can be classified as "crude" or "dilute" on the one hand, and "refined" or "concentrated" on the other. Experience shows that the refined extracts are more reliable than the crude, presumably because greater care is taken in clinical testing and assay. Intensive liver treatment, such as would be administered in a refractory case of pernicious anaemia, would formerly have implied 4 c.cm. of refined extract of liver intramuscularly every day for six weeks. To-day the injections would be supplemented or even replaced by proteolysed extract of liver, 1/2 oz. three or four times a day by mouth, and the proved superiority of oral therapy of this kind to any form of parenteral therapy has quashed the arguments that have been advanced on behalf of crude intramuscular extracts.

Dermatitis of Palms

Q.—*Please advise on treatment of dermatitis of both palms. There is intensive itching, then a cracking and desquamation of the skin. Duration off and on for nearly 20 years at intervals, now constant for the last 12 months and extending to the palmar surface of fingers and thumbs. Very unsightly; various ointments tried; patient's age 74.*

A.—In the absence of a more detailed description the following general rule is offered as an aid to diagnosis and treatment. Chronic skin diseases of the palms may be approximately divided into three groups.

1. Local or general infection—i.e., ringworm or syphilis. The first is confirmed by microscopical detection of the fungus in the scales, or in exceptional cases by culture; the second, by a positive Wassermann reaction. Appropriate treatment includes (*a*) Whitfield's ointment, and (*b*) antisyphilitic remedies.

2. The second group represents certain generalized skin diseases in which the palms may be affected, such as eczema and psoriasis; the presence of the eruption elsewhere provides the key to diagnosis. The treatment is that appropriate for the general condition.

3. In the third group the non-committal diagnosis of idiopathic hyperkeratosis or dermatitis is allowable.

In the second and third groups *x* rays given in small doses by an expert familiar with the very special technique are often curative. Crude coal tar 6% in zinc paste, a rather dirty but valuable remedy, can also be tried. As the palmar skin is constantly in motion and also constantly subjected to various degrees of trauma, rest and protection may be required—by an occlusive dressing of linen or gauze spread with 3% ichthyol ointment held in place with elastoplast and kept in position unchanged for a week, unless there is evidence of intolerance. Rare or comparatively uncommon processes such as arsenical hyperkeratosis or acrodermatitis are not covered by the above. The allergic dysidrotic eruption of fingers and palms secondary to ringworm between the toes does not seem to fit into the clinical picture as described in the question.

Penicillin and Virus Infections

Q.—*Has penicillin ever been used in the treatment of chronic encephalitis, or the sequelae of encephalitis, such as Parkinsonism, and if so with what result?*

A.—Parkinsonism and other sequelae of encephalitis are degenerative conditions on which neither penicillin nor any other anti-infective agent could conceivably have any effect. Even in the acute stage virus infections of the central nervous system are, so far as is known, unaffected by penicillin; there is very little evidence that penicillin has any action on filterable viruses.

Nervous Reaction after Bombing

Q.—*A patient was in his house when it was bombed two years ago. He now complains of being very tender to touch; his arms and neck are red at times and burn. He cannot hold anything, and feels at times as if his skin was coming off. He gets very itchy when he touches any part of his body. He is healthy in other respects. Can you advise on treatment?*

A.—In such cases we almost invariably find that there is a period of amnesia; it may be the actual explosion, it may be the thought that this was the end. Part of the experience is therefore dissociated, and it is this dissociated part which perpetuates the nervous condition. The symptoms of tenderness and burning are almost certainly experiences which he felt at the time, and which, because they are dissociated, tend to recur. In other terms, there is an unsolved problem in his personality which will not allow him to rest till he solves it—a problem of fear. The best form of treatment in such cases is "abreaction"—namely, to recover the forgotten part of the experience with all its terror and pain, and when it is brought to the light of consciousness the patient is relieved in himself and cured of his symptoms. This requires the skilled treatment of a psychotherapist, either by hypnosis or by free association. But if such is not available, "narco-analysis" may be tried, and an attempt made to recover the experience under light narcosis of evipan or pentothal. The patient should be put only just over, and then urged to remember the whole experience and live it through again. Several treatments are usually required by whatever method.

Extrasystoles

Q.—*Why should a meal produce premature beats? What are the significance and cause of extrasystoles in a man of 68 with arteriosclerosis and blood pressure 220, and in a young female patient who is disturbed after meals and at night (preventing sleep) by a sensation as if the heart gave a kick or turned over, and by occasional long pauses? What is the treatment of the elderly and the young?*

A.—Premature beats may result after a meal because of the increase in work due to the increase in cardiac output, or perhaps reflexly from the stomach, possibly through gastric distension.

The cause of extrasystoles in a man of 68 is probably ischaemic changes in the myocardium consequent upon sclerosis of the coronary arteries. In themselves they have but little significance, although a patient with them is, perhaps, in slightly worse case than a similar patient without. In a young patient the cause cannot be ascertained without further investigation. A source of toxin should be sought for; the intake of tea and coffee considered, the consumption of tobacco remembered, and the diet perhaps regulated. The treatment of the extrasystoles themselves consists in possibly removing the cause, if it can be found, and in using sedatives to reduce the irritability of the myocardium. Bromide, barbitone, quinidine (not now obtainable), are most likely to be successful. Removal of anxiety caused by extrasystoles is most important. Many patients have them unaware; treatment is only needed if they cause annoyance.

Instruction about Menstruation

Q.—*What are the current views, both gynaecological and psychological, regarding the wisest approach to the subject of menstruation on the part of those responsible for girls' boarding schools? I refer in particular to the questions of (a) games-playing, and (b) instructional guidance.*

A.—Instruction should have two main objects—to give the girls a simple but truthful account of the physiology of menstruation and its significance, and to impress them with the fact that it is not an illness but a natural process which is not incapacitating in any way. The achievement of such aims will of necessity also require the discrediting of the many false ideas and superstitions which are still widely current.

There are many ways of approach, and those responsible for giving instruction will naturally choose one which they can best handle, and they may with advantage vary it to suit the individual child. Information on reproduction is often the best starting-point—information which the child may already have received before entering school. The next step is to point out that the young of all species are incapable of reproduction, which capacity only comes when they are fully developed in other respects. The onset of menstruation then becomes a sign that genital development is taking place, a sign of approaching womanhood. Having received a reasonable explanation, most girls will accept menstruation as a feminine characteristic and cease to take much further interest in it, but, lest they should discuss it among themselves and compare notes, it is perhaps wise to point out that, as in other features, individuals vary widely in their menstrual function—the age of menarche, the periodicity, duration and amount of flow, etc. It is important that they should also realize that the menstrual discharge consists essentially of healthy blood, and not of any noxious material or waste product the excretion of which is necessary for bodily well-being. It follows from this that the suppression of menstruation does not have any of the general ill effects which popular fallacies allege.

The management of girls during menstruation should follow the teaching that it is a normal process which should not interfere in any way with their ordinary life. They should be expected and encouraged to continue their studies, games, and other activities of all kinds (including washing of hair, taking baths, etc.), and only in exceptional circumstances should a girl be allowed any relaxation from the ordinary school routine. Games and other forms of exercise are especially valuable, because they not only distract the girl's attention and discourage any idea that she is "poorly," but also prevent any tendency to pelvic congestion. The only exception is perhaps swimming—not because cold water is harmful, but for aesthetic reasons only.

Instruction should also be given in the matter of personal cleanliness, and the girls made to bath daily and to change sanitary towels and underclothing frequently. Douching at the conclusion of menstruation as taught in some Continental schools is, however, to be deprecated as both unnecessary and potentially harmful.

There remains the ever-debatable question as to who should give information on these matters—parent, doctor, or teacher? The answer varies, no doubt, with different cases, but surely the ideal is that it should be given by the mother, informally and piecemeal, as the occasion presents, and before the girl reaches puberty or enters boarding school. Unfortunately some mothers omit to give any information, and many more, through ignorance, give wrong advice. The omission can be remedied fairly easily, but the school staff may find it very difficult to eradicate false impressions which a girl has received from someone in whom she has implicit trust.

Large Vitamin Dosage

Q.—*Is there any proof that large quantities of vitamins are of any value? In the early days I was taught that Hopkins regarded the vitamin action as catalytic and only minute traces were necessary for life and health. Is this view no longer held? This is a humble inquiry to those who are better informed from a practitioner confessing ignorance.*

A.—I assume that the questioner means by "large," quantities above those recommended by, for example, the National Research Council, U.S.A. On the whole the reports indicate that no benefit is derived from the addition of extra vitamins to a diet that is already adequate. The following are examples.

Cowan, D. W., *et al.* (*J. Amer. med. Ass.*, 1942, **120**, 1268): no difference in incidence and severity of colds when extra vitamin A, aneurin, riboflavin, ascorbic acid, and vitamin D given.

Keys, A., and Henschel, A. F. (*J. Nutrit.*, 1942, **23**, 259): no difference in young men taking strenuous exercise when extra aneurin, nicotinamide, calcium pantothenate, riboflavin, pyridoxine, and ascorbic acid given.

Bierman, W. (*Arch. physical Therap.*, 1940, **21**, 267): colour vision not improved by large doses of vitamin A.

Johnson, R. E., *et al.* (*J. Nutrit.*, 1945, **29**, 155): no improvement in physical capacity in man receiving 300 mg. of ascorbic acid in addition to a diet supplying 56 to 109 mg. per day.

The subject is discussed by Keys, A. (*Fed. Proc.*, 1943, **2**, 164).

In deficiency diseases large doses are needed in order to make up the deficit. Also it is possible that large doses may have some stimulating effect comparable to that of large doses of iron, which may raise the haemoglobin in the blood of apparently normal people.

English Qualifications in Canada and U.S.A.

Q.—*Is an M.R.C.S., L.R.C.P. allowed to act as locumtenent in general practice in Canada? What is the minimum time during which an M.R.C.S., L.R.C.P. can qualify as a medical practitioner in any one State in the U.S.A.? Is any concession made in respect of an English diploma?*

A.—There is a separate medical licensing law in each Province of Canada. Reciprocal agreements with regard to medical practice exist between this country and the Provinces of Alberta, Manitoba, Nova Scotia, and Prince Edward Island, and a holder of the diplomas of M.R.C.S.Eng. and L.R.C.P.Lond., who is registered in the *Medical Register* kept by the General Medical Council, should be able to obtain licences to practise in these four Provinces without further examination. In the remaining Provinces he would probably be required to pass an examination held either (1) by the Provincial Licensing Authority (usually entitled the College of Physicians and Surgeons), or (2) by the Medical Council of Canada and accepted by the provincial authority in lieu of its own examination.

It is understood that a majority of the United States accept the Diploma of the National Board of Medical Examiners of the United States, and that the English Conjoint Board have an agreement with the National Board of Medical Examiners whereby holders of the diplomas of M.R.C.S.Eng. and L.R.C.P.Lond. are admitted to the examinations of the National Board without any further course of study.

Albuminuria in Pregnancy

Q.—*I have noticed that in cases of advanced pregnancy with albuminuria the onset of labour was immediately preceded by an increase of the amount of albumin in the urine. Is there any connexion between albuminuria and onset of labour?*

A.—Albumin is frequently found in the urine during the course of labour, and is said to occur in one out of every three labours and to be especially common in primigravidae. Prolonged and difficult labour, a rise of temperature, and the administration of anaesthetics during labour are said to predispose to albuminuria. The amount is usually slight and should not exceed 1 part per 1,000. The cause of the albuminuria in labour has been variously attributed to the hard muscular work involved, to the rise of blood pressure which is a normal concomitant of labour, and to the escape of chorionic villi into the maternal circulation, the result of the powerful contractions of the uterus. Whatever the explanation may be, I know of no observations on albuminuria immediately prior to the onset of labour.

The causes of albuminuria in pregnancy are well known. It is, of course, important to ensure that it is a true albuminuria and to exclude contamination of the urine by vaginal discharge. In most cases some cause can be determined—e.g., toxaemia, pyelitis, chronic nephritis, etc.; in which case there will usually be some other sign, such as a rise of blood pressure.

INCOME TAX

Replacement of Car: Allowances

The present high cost of motor cars and the increased amounts which have been obtainable recently for second-hand cars have raised questions on which some general guidance may be desirable. When a practitioner decides to dispose of a car and buy a new one it frequently happens that the amount he receives for the old car—by way of set-off against the cost of the new one—is considerably greater than that portion of the cost of the old car which has not been allowed against his past earnings in the form of a depreciation allowance. For instance, the old car may have cost £500, and £400 may have been allowed over a period of years as "depreciation"; if the car is now sold for £225, the practitioner is in the position of having been allowed to deduct £400 depreciation although over the life of the car the cost has been only £500−£225=£275. The question which arises is whether any adjustment should be made for what may appear to have proved an excessive allowance of £400−£275=£125, either by altering the past or future normal allowances or by treating the £125 as in some way amounting to an assessable profit. The answer is quite simple. The £125 is an untaxable advantage which has accrued through the capital appreciation of an asset used in the practice. If the owner were trading in cars the position would be different, but as the car was part of the equipment and not part of a trading stock no assessable profit arises from the advantageous sale. The depreciation allowances in past years may be assumed to have correctly represented "the diminished value by reason of wear and tear during the year," and the subsequent sale price of the car is relevant only as regards any claim to "obsolescence" allowance. In the circumstances no such claim arises, but the statute affords no authority for the conception of a *negative* allowance, and therefore no adjustment of past or future normal depreciation allowances would be justified. In such a case, therefore, as the instance suggested above the practitioner has, in the result, been fortunate enough to obtain some untaxable advantage in connexion with the old car, and is entitled to claim depreciation on the full cost of the new car, and not on the cost as reduced by the quasi-profit on the old one.

Additional Share of Partnership Profits

J. W. acquires an increase in his share of the profits of the practice as from Oct. 1, 1945. How does this affect the tax payable for the year ending April 5, 1946?

⁂ The profits of the practice are assessable on the basis of the amount of the profits for the year preceding April 5, 1945. But that assessment is divisible between the partners according to their respective shares for the current financial year. J. W. will therefore be responsible for tax on his increased share as from Oct. 1, 1945, and the share of the tax payable by him in January and July, 1946, will be increased accordingly.

LETTERS, NOTES, ETC.

Doctors and the Social Trend

Dr. Geoffrey Duckworth (London, W.1) writes: Possibly Dr. P. G. S. Davis (Sept. 22, p. 405) read my letter hastily. Had he read it thoughtfully he would surely not have omitted the essential qualification, now in italics, ". . . *the Labour Party's idea of* . . ." Dr. Davis imagines I assumed that all the Liberals would have opposed the (Labour) measure. I merely reminded readers that under proportional representation the Labour Party would not have had a majority. How can this be called a decisive vote in favour of the Labour Party's idea of a National Health Service?

Alphabetical Pride

Dr. Kenneth McFadyean (London, S.E.24) writes: I wonder if you can enlighten me as to the purpose, if there be one, of the newly developed and nauseating habit of our profession signing their personal letters with the appendage of all the qualifications which they possess. I recently received a letter from a colleague starting with "Dear Dr." and ending "yours sincerely," and following his signature appeared these qualifications: M.B., B.S., D.A., D.C.H., D.P.H., D.M.R., D.M.R.E.

Tuberculosis Death Rate in Wales

In our issue of Sept. 15 (p. 363) appeared a short account of a report issued by the Northern Ireland Branch Council of the B.M.A. We quoted from this report the figure for the annual death rate from tuberculosis for Wales as 958 per million. We are informed, however, by the Principal Medical Officer of the King Edward VII Welsh National Memorial Association that the most recent death rate from tuberculosis in Wales—namely, for 1944—is 715 for all forms of the disease. In 1938 it was 812, and to reach a figure approaching the 958 quoted in our article one has to go back to 1934, when the death rate in Wales was 913.

INFLUENCE OF GALVANIC STIMULATION ON MUSCLE ATROPHY RESULTING FROM DENERVATION

BY

E. C. S. JACKSON
Flight Lieutenant, R.A.F.V.R.

AND

H. J. SEDDON
Nuffield Department of Orthopaedic Surgery, Oxford

For many years the role of electrical stimulation in the treatment of lower motor neuron lesions has been the subject of lively controversy; and since the beginning of the war interest in this form of treatment has been quickened by the occurrence of thousands of cases of peripheral nerve injury. The results of animal experiments and of observations in man, though at times conflicting, are now consistent enough to warrant the formulation of certain conclusions.

1. Muscle atrophy begins very soon after denervation and proceeds rapidly at first, the rate gradually decreasing the longer the time after denervation.
2. Interstitial fibrosis is a constant feature of denervation atrophy and, should re-innervation occur, the greater the atrophy and fibrosis the poorer the ultimate functional recovery (Bowden and Gutmann, 1944). It is therefore logical to assume that if atrophy can be prevented or at least controlled there is a greater likelihood of recovery being satisfactory.
3. Furthermore, since there is as yet no evidence that fibrosis is irreversible, the treatment designed to prevent it should be started as soon as possible after denervation and continued until re-innervation has occurred.
4. The precise nature of denervation atrophy is still undetermined. It is reasonable to suppose that disuse and a consequent impairment of nutrition play an important part, but this is not the whole story. Fibrillation, the unceasing irregular contraction of individual muscle fibres—a phenomenon always observed in denervated muscle—has been regarded as an important factor; it has been supposed that this incessant activity tires out, and so causes atrophy of, the denervated muscle. From this it would follow that artificial stimulation of the muscle could only make matters worse.
5. Nevertheless it has been conclusively shown that muscle-wasting can in fact be controlled to a very considerable extent by repeated electrical stimulation, using a stimulus of comparatively long duration. Although galvanism has several disadvantages—the discomfort it causes being one of the most important—it is still the only type of stimulus of long duration generally available, and it was for this reason that it was used in the investigation to be described.
6. To be effective the treatment must be intensive, both in the strength of stimulus and in the number of contractions elicited at each session; it must be continued over a long period.
7. Galvanism is of greater value in the prevention of wasting when it is applied soon rather than late after denervation, though Gutmann and Guttmann (1942, 1944) found that even the most intensive treatment did not altogether prevent the atrophy that occurred in rabbits during the first few weeks after denervation.
8. In the treated muscle (Gutmann and Guttmann, 1942, 1944) the muscle fibres remain comparatively large, the interstitial tissue does not increase to any great extent, and if re-innervation occurs functional recovery is good. In untreated muscle the fibres shrink rapidly, fibrous tissue appears between them, and recovery is poor.

Unfortunately a number of factors must make us pause before concluding that equally satisfactory results will follow the employment of galvanism clinically—so much so that without some positive demonstration of its value in the treatment of patients with lower motor neuron lesions there would be little justification for recommending the general application of a treatment which is uncomfortable, time-consuming, tedious, and expensive. The rate of wasting in man at various periods after denervation is unknown. Adequate stimulation is limited by the large size of many muscles, by the pain produced by powerful electrical stimuli, and by an intolerance peculiar to certain patients whose skins are naturally sensitive or who are suffering from a nerve lesion that has itself caused cutaneous hypersensitivity.

Almost all of the methods used for the assessment of the value of galvanism in animal experiments are inapplicable in man, and it was therefore necessary to be content with a comparatively simple and not very accurate method of estimating muscle-wasting. The work about to be described was carried out by one of us (E. C. S. J.) during the period Jan., 1942, to July, 1944. The results will be reported in full elsewhere, but the importance of the conclusions to which they have led seems to be such as to warrant the immediate publication of a short undocumented account of the findings

Method

Measurements of the volume of the hand by a simple fluid displacement method* were made in a number of cases of paralysis of muscles of the hand. In all, 164 patients were examined; in only 92 was it possible to obtain readings with sufficient frequency to be of value, and of these only 54 were suffering from complete nerve lesions. The results reported are concerned with these 54 cases. Some were treated with galvanism; in the rest stimulation was withheld though in other respects the treatment was identical.

Ulnar paralysis was present in every case; in 18% of those treated with galvanism, and in 20% of those not so treated, there was also paralysis of the muscles of the hand supplied by the median nerve. The cases were divided into groups according to the type of lesion and the time that had elapsed between injury and the first volumetric measurement. Each small group was subdivided as evenly as possible; half of the cases were treated with and the other half without galvanism. In the treated group galvanism was given on six days in each week, and each treatment consisted of 90 stimuli to each small muscle group (e.g., a pair of interossei in an intermetacarpal space), the current used being sufficient to produce a good contraction. The stimuli were given at the rate of 30 a minute, with short intervals between each group of 30 stimuli so as to avoid fatigue. Records were kept of the return of voluntary power, the electrical reactions (using Bauwens's machine), and electromyographic changes. The wasting was measured by immersing the hand in industrial alcohol up to a tattooed mark on the wrist and weighing the amount of fluid displaced. With a co-operative subject there was an error of only 0.5%. There were greater errors due to physiological variations in the volume of the hand and in some cases to unsteadiness of the patient's arm; these, however, were insignificant when compared with the changes in volume due to wasting. Since most patients were first seen some time after the original injury no attempt at absolute estimations was made; we concerned ourselves only with the changes between one examination and the next. The results reported are limited to the period of complete paralysis. When voluntary power is returned the progress of re-innervation is subject to so many variable factors that no definite conclusions can be drawn from the volumetric changes that occur during recovery.

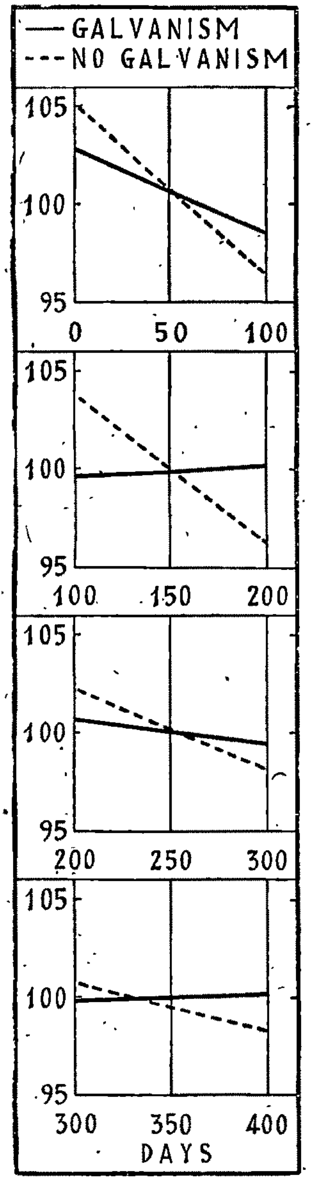
---

* The machine which we devised was hopelessly inaccurate, and it was impossible to proceed until a much more accurate, but still very simple, machine had been designed and made for us by Dr. K. Mendelssohn and Dr. D. S. Evans—to whom we are greatly indebted

Each reading was expressed as a percentage of the mean volume of the hand during the total period of observation.

Results

The results have been summarized and are shown in the accompanying Charts.

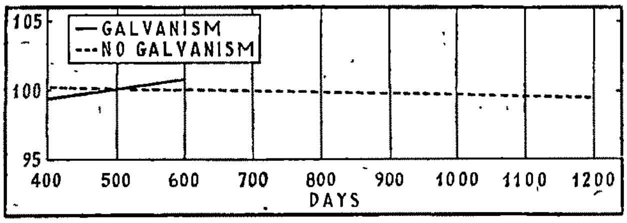


Comment on Charts.—In each period up to 400 days there was a steady loss of volume in the untreated muscles, the rate of loss gradually diminishing until, after 400 days, there was little change, the muscles having by this time wasted to such an extent that further shrinkage could hardly occur. Except during the first 100-day period, galvanism was almost completely effective in preventing wasting; but there was no increase in volume except in the 400 + day period, and here the apparent increase may have been due to chance.

Discussion

In spite of inaccuracies due to vasomotor changes, oedema, and the like—though their significance is greatly reduced when frequent volumetric measurements are made—there is no doubt that the volume of the hand is better maintained where the paralysed muscles receive regular galvanic stimulation. At first sight the differences in volume seem disappointingly small, but they are very striking to the naked eye and are great in relation to the volume of the muscles alone. It has not yet been possible to establish the relation between the volume of the musculature of the hand and that of the hand as a whole, but it is tolerably certain that the muscles constitute less than one-quarter of the total volume of the hand. Thus it is safe to multiply the observed differences by four—perhaps five or six.

From these experiments it was clear that the general course of wasting is similar to that seen in experimental animals. The beneficial effect of galvanism is most noticeable soon rather than late after denervation, so the earlier treatment is started the better. However, galvanism does little if anything towards increasing muscle volume—at best it prevents the otherwise inevitable decrease—so that whatever has been lost through delay cannot be regained. During the first 100 days galvanism does not prevent wasting, it only retards it; and, although the results in the 0–100 days group are not so reliable statistically as in the other groups, detailed study of the few very early cases bore out the conclusion of Gutmann and Guttmann that the wasting that occurred soon after denervation could not be entirely prevented. At the same time it must be remembered that without galvanism wasting proceeds faster in the first 100 days than at any other time. The lesson to be drawn from this is that it is never too soon to begin galvanic stimulation, and if the paralysed part has to be enclosed in plaster windows should be cut so as to permit the early application of electrodes to the affected muscles.



Although it was not possible to formulate any general conclusion, the observation of individual cases strongly suggested that recovery was better in cases treated with galvanism than in those in which no attempt was made to check muscle-wasting. Furthermore, electromyographic observations showed that the delay between the appearance of motor units in a paralysed muscle and the first flicker of voluntary contraction was less in cases in which regular galvanic stimulation had been carried out. Recordings were also made in cases treated three times a week—most of them at other hospitals, where it may be assumed there were considerable variations in technique. The results were intermediate between those found in cases treated six times a week and those receiving no treatment at all.

While it is comforting to know at last that galvanism is of real value, it is indeed unfortunate that success depends so largely on the frequency of treatment. However, it is possible to train patients in the use of a galvanic machine, and if suitable apparatus can be manufactured at a reasonable price intelligent and co-operative patients might be encouraged to treat themselves at home. In a few cases this has already been done with success.

Another important problem awaits solution. In this investigation ulnar paralysis was chosen because of the ease with which the volume of the hand may be measured. But one cannot overlook the fact that the muscles of the hand are more accessible to stimulation than the much larger muscles of forearm, arm, leg, and thigh. When large masses of muscle are stimulated with tolerable currents the contractions observed are often confined to the more superficial fibres; thus it may well be that here the influence of galvanism on wasting is less striking than in the intrinsic muscles of the hand. This point is now being investigated in cases of radial paralysis, with the help of a larger and more elaborate machine capable of measuring the volume of the hand and forearm.

Summary

It has been proved experimentally that the wasting of denervated muscle—a process prejudicial to recovery—can be prevented to a considerable extent by regular electrical stimulation of the muscle with stimuli of long duration, such as are provided by a galvanic battery.

A fluid-displacement method was used to measure the volumetric changes in the hand in cases of ulnar paralysis, some treated with, others without, galvanism.

It was found that the application of 90 stimuli daily for six days a week was almost wholly effective in preventing wasting except during the weeks immediately following denervation, though even during this period such treatment reduced the rate of wasting. The stimuli were strong enough to produce a brisk contraction, and were given at the rate of 30 a minute, with an interval of one minute between each group of stimuli to permit recovery from any possible fatigue.

There was no evidence that electrical stimulation increased muscle volume, and hence it is important to start treatment as soon as possible, since whatever has been lost through delay cannot be regained.

There is no doubt that in ulnar paralysis daily galvanic stimulation is well worth while, and that the treatment should be continued until voluntary power returns.

It is not yet known whether galvanism is equally effective in preventing wasting in large masses of muscle, since a tolerable stimulus does not affect all parts of a large muscle mass equally, the deep fibres tending to escape altogether.

CHANGES IN HUMAN VOLUNTARY MUSCLE IN DENERVATION AND RE-INNERVATION

BY

R. E. M. BOWDEN, M.B., B.S.

(*Peripheral Nerve Injury Unit, Department of Orthopaedic Surgery, Oxford*)

A study of the changes in human voluntary muscle during denervation and re-innervation is essential for a proper understanding of lower motor neurone lesions, especially peripheral nerve injuries. There are significant changes in structure and physiological properties. The subject will be considered from the point of view of histology, electrical reactions, electromyography, and treatment of paralysed muscles.

Structural Changes

For the sake of clarity some of the characteristics of a normal muscle must be mentioned first. A voluntary muscle is composed of numerous fasciculi made up of cross-striated fibres arranged in compact parallel bundles. The nuclei are for the most part arranged at the periphery of the fibres. Some preparations show minute granules regularly spaced at the level of the dark bands. The nerve fibres can be clearly seen, and the axons are myelinated to the point where they enter the motor end-plates. A single nerve-cell, its axon, and the muscle fibres innervated by it constitute the motor unit. The branching of the axon occurs close to the point of entry into the muscle. The blood supply is plentiful, for the capillary network is rich. All these structures are supported in delicate and sparse connective tissues.

In the early stages (one to three months after denervation) there is a loosening of the compact arrangement of the fibres, an apparent numerical increase of the nuclei, and little change in the connective tissue. The blood vessels appear to be dilated, indicating stasis of the circulation. The nerve fibres undergo Wallerian degeneration, and when all the debris of the disintegrating fibres has been removed the empty Schwann tubes remain and can be traced to the empty motor end-plates.

From three months onwards there is a progressive shrinkage of the muscle fibres, cross-striation fades from the earliest days, and the granules become increasingly apparent and irregularly arranged. The vessel walls thicken and some are completely blocked. There is an increase of connective tissue, apparently beginning around the vessels and spreading throughout the muscle, invading and finally obliterating the terminal Schwann tubes and motor end-plates. As the muscle fibres atrophy they are replaced by fat and connective tissue. Ghosts of fibres, a few capillaries, and the larger nerve trunks may be seen surrounded by fibrous tissue, and finally the muscle may resemble tendon, or there may be a few scattered connective-tissue tubes containing granules—all that remains of the muscle fibre.

The time course of these changes is of great importance, for upon the reversibility of the changes in the muscle fibres depends the recovery of function. The changes are predominantly those of atrophy and not degeneration. Fibrous tissue seems to wage a war of attrition upon muscle fibres. Up to one year after denervation it is possible to expect a fairly good degree of functional recovery; from then onwards the prognosis deteriorates, and as a rule from three years onwards the prospects are exceedingly poor. The fibres are atrophic and have lost their characteristic structure; connective tissue is strangling and obliterating the contractile tissue, vessels and empty motor end-plates, and Schwann tubes. There are exceptions to this statement, for there are notable individual variations: sepsis, age, mobility of the limb, and physiotherapy influence the rapidity of the changes.

The nature of the lesion in the nerve influences the degree of functional recovery profoundly, as this determines the number and maturity of the axons which ultimately reach the end-organs. In axonotmesis (Seddon, 1942, 1943; Gutmann and Sanders, 1943) the supporting tissues of the nerve at the site of the lesion are intact, although the trauma has been sufficient to cause complete peripheral degeneration of the axons. There is minimal intraneural scarring, and regeneration of the fibres occurs spontaneously and without obstruction down the original pathways. The time of denervation depends almost entirely upon the level of the lesion above the muscles (Gutmann, Guttmann, Medawar, and Young, 1942; Seddon, Medawar, and Smith, 1943). The motor end-plate is intact, cross-striation is visible, and atrophy of the fibres is slight. Good powerful independent muscle action is restored in such cases and there is an apparent complete reversal of the atrophic changes in the muscle although the pattern of innervation is slightly abnormal. Where the nerve has been more seriously damaged there may be partial disruption of the Schwann tubes and scar formation. Here some nerve fibres will be obstructed and there will not be an even advance of regenerating axons. Some permanent weakness and atrophy may be expected and there may be impairment of independent action of the muscles.

In complete division of the nerve no recovery can take place without surgical intervention. There is inevitable delay in re-innervation: at the site of the suture scar tissue is present in varying degrees. Moreover, there is unavoidable confusion of the axons at the suture line; therefore regeneration cannot take place down the original Schwann tubes. Some axons from the central stump may never penetrate the scar, others may escape laterally, and those that reach the peripheral stump may enter abnormal channels. The number of nerve fibres reaching the end-organs is diminished. If the muscle has been denervated for some considerable time the finer Schwann tubes are blocked and the motor end-plates will have disappeared. The regenerating nerve fibres may escape from the Schwann tubes, and they run for long distances between and across the muscle fibres seeking to make new connexions; some fail completely, and are therefore wasted (Gutmann and Young, 1944; Bowden and Gutmann, 1944). The reversal of changes in muscle fibres is hampered by the time of denervation and by incomplete and sometimes incorrect re-innervation. Full power and independent action can never be restored. Where delay has been too great the muscle may be incapable of recovery and the best degree of re-innervation will be of no avail (Bowden and Gutmann, 1944).

Electrical Reactions

Associated with the structural changes there are certain important changes in the function of the denervated muscle. Loss of tone and voluntary and reflex action is immediate and there is a more gradual change in electrical excitability. Each tissue has a characteristic excitability. Some are quick tissues—that is, they respond to electrical stimuli of low intensity and short duration: nerve is an example of such a tissue. Others are slow—that is, they will respond to stimuli of short duration only if the intensity is great.

A normal muscle responds to percutaneous faradic stimulation at low intensities; this stimulus is of short duration. The muscle contracts because it is receiving impulses via the intramuscular nerve twigs. As the nerve degenerates its excitability decreases and is ultimately lost. At the same time the muscle is losing the power of responding to faradic stimulation. The muscle fibres themselves are being stimulated, and the faradic response either disappears or is obtained only with a high current; the galvanic response, however, is much more easily elicited and the contraction becomes sluggish. This quantitative and qualitative change was described by Erb (1876) as the reaction of degeneration (but, as we have seen, the early changes in the muscle fibres do not merit description as degenerative). The sluggishness of the galvanic response is possibly due to the stimulus being conducted by muscle fibres and not by nerve; the rate of conduction in muscle is slower and all the fibres cannot contract simultaneously. During denervation the threshold to galvanic stimuli rises with loss of contractile substance and may finally disappear altogether if atrophy is advanced. The failure to elicit a galvanic response in the absence of oedema indicates serious atrophic change in a muscle. During re-innervation there are changes in excitability as the nervous element reappears, but it is possible for there to be a good functional recovery while the electrical reactions are still abnormal. (Reports of a further clinical survey will be published in due course.)

Electromyography

There is another interesting alteration in electrical activity which is of great significance in diagnosis ; but, unlike electrical reactions, it can be of considerable prognostic importance. The action currents of contracting muscles can be recorded—the electrocardiogram is a well-known example. By electromyography it is possible to record the action currents in a voluntary muscle.

For about 12 to 28 days after denervation there is no recordable electrical activity in human muscle on attempted movement or at rest. From 12 to 28 days after denervation fibrillation occurs: this is shown by rhythmic fine spikes totally unrelated to attempted voluntary contraction. The exposed surface of such a muscle if observed by reflected light will show numerous small scattered twitches. Fibrillation persists as long as any contractile denervated fibres remain, or until re-innervation is taking place, but in the early stages of re-innervation a muscle which has previously shown vigorous fibrillation becomes silent. Motor-unit action potentials may precede recovery of voluntary function by as much as three months, and an isolated observation of this sort is no guarantee that further re-innervation is going to occur.

The finding of both fibrillation and motor-unit action potentials indicates a partial or recovering degenerative lesion of the lower motor neurone (Weddell, Feinstein, and Pattle, 1943, 1944 ; Bowden, unpublished).

Treatment

We have seen that electrical reactions and electromyography may be of help in diagnosis and to some extent in prognosis. The histological findings have shown that in the muscle itself atrophy of the muscle fibres and connective-tissue proliferation are the enemies of recovery. Surgical repair, if necessary, should be undertaken as soon as possible. There is experimental and clinical evidence that atrophy of muscle can be retarded by activity induced by adequate electrotherapy. The contraction of the muscle is essential ; therefore faradic stimulation of denervated muscle is useless and a waste of time. Denervated muscle responds to galvanism, and this is therefore one method of treatment.

In a series of rabbits both the left and right tibialis anterior were denervated for the same length of time. One side was treated daily with galvanism, the other was untreated ; and there was considerable difference in the naked-eye appearance of the muscles. The histological picture was even more impressive: the diameter of the treated muscle fibres is much greater than that of the untreated side and the formation of fibrous tissue is minimal (Gutmann and Guttmann, 1942, 1944). This is a most convincing proof of the value of regular adequate electrotherapy. Can this experimental finding be applied clinically ?

Dr. Shirley Jackson investigated the value of galvanism in a series of cases of ulnar nerve palsies (personal communications ; work in press). Volumetric measurements were made at intervals. It was seen that atrophy is most rapid in the early stages of paralysis, and that electrotherapy does not wholly prevent atrophy ; it can only retard the rate. At no time was there an increase in volume of the hand in the absence of re-innervation. Therefore it is essential that electrotherapy not only should be regular and adequate but should begin as soon as possible after injury.

Connective-tissue formation is retarded by physiotherapy, but it cannot be entirely prevented. The late sequel of connective-tissue formation is contracture of the paralysed muscle. Whilst contractures can and do form in active unopposed muscles, they may occur in paralysed muscles, either early or late in the course of denervation. They can be wholly prevented by daily movements throughout the whole range of the joints of the limb. Splinting of paralysed limbs is never done to obtain immobilization unless there is a fracture or an unhealed wound ; the object is to prevent overstretching and to encourage activity by compensating for the paralysis, if this is possible.

The author is indebted to the British Orthopaedic Association for permission to publish this paper, which was read at the association's meeting on Dec. 15, 1944. The work discussed has been carried out by members of the peripheral nerve injury unit, Department of Orthopaedic Surgery, Oxford, under the direction of Prof. H. J. Seddon, and in conjunction with members of the Department of Zoology and Comparative Anatomy, and of the Department of Human Anatomy, University of Oxford. A fuller discussion, and bibliography, will be found in the papers quoted.

VALUE OF SUPPLEMENTS OF VITAMIN C IN PREVENTING LACTATIONAL MASTITIS

BY

A. A. FULTON, M.D., D.P.H.

Maternity and Infant Welfare Medical Officer, Corporation of Dundee

One theory put forward for the high incidence of lactational mastitis in an industrial Scottish town (Fulton, 1945) was that a deficiency—probably due to wartime restrictions—in some food factor, or factors, was a predisposing cause. Nixon (1941) has suggested that there is a relationship between dietary deficiencies and puerperal infections, and has cited as evidence the fact that during the last war mortality from puerperal fever in Germany was almost doubled as a result of the blockade. One of the most obvious of wartime food curtailments in this country is shortage of fresh fruits and vegetables, the chief source of vitamin C. Widdowson and Alington (1941), in studying middle-class diets, have shown that in 1935 fruit supplied ten times as much vitamin C as it did in 1941 and that the average vitamin C intake in 1935 was more than double what it was in 1941.

At the time when this experiment was begun (Dec., 1941) the following assumptions could reasonably be made.

(1) There was a high, if not an increased, incidence of mastitis.

(2) The incidence of mastitis appeared to be greater in the winter months (Moon and Gilbert, 1935).

(3) Some degree of vitamin C deficiency was common. Many writers had brought forward evidence to support this view (Harris and Ray, 1935; Abbasy *et al.*, 1935; Orr, 1936; Harris *et al.*, 1936; Portnoy and Wilkinson, 1938; Harris, 1940a; Youmans, 1941)

(4) Hypovitaminosis C was likely to have increased under wartime conditions. This has since been proved by Widdowson and Alington (1941), Harris (1942), Francis and Wormall (1942), and Widdowson and McCance (1942).

(5) Hypovitaminosis C is more likely to occur during pregnancy and lactation. There is evidence that vitamin C requirements are increased during these periods (Harris and Abbasy, 1937: Smith, 1939; Neuweiler, 1935).

(6) There is a seasonal fluctuation in the intake of vitamin C, as fresh fruits and vegetables are more plentiful in the summer and autumn months. Evidence of this has since been published by Harris (1942), McNee and Reid (1942), Harris and Olliver (1943), Prunty and Vass (1944), and Craig *et al.* (1944).

(7) The time of seasonal increase in the incidence of mastitis (the winter and spring months) roughly corresponds to the period when intakes of vitamin C are lowest.

(8) Lack of vitamin C diminishes the resistance to infection (Harris, 1937; Smith, 1939; Harris, 1940b; Youmans, 1941).

If these assumptions were accepted there seemed to be some justification for postulating that vitamin C deficiency might be responsible, at least in part, for the occurrence of mastitis. An experiment was devised to attempt to verify or disprove this hypothesis. Although, admittedly, a diet functions as a whole and deficiency of one constituent only is unlikely to occur, it was thought better to investigate the effects of varying the intake of one single factor in order to attempt to obtain a clear-cut result regarding that factor. The project was to give one group of pregnant women supplements of ascorbic acid and to compare them, especially as regards the incidence of mastitis, with a group of women, similar in other respects, who did not receive supplements.

Plan of the Experiment

There are two ante-natal clinics in the town concerned, each serving approximately half the town and attended by patients similar in most respects, including social status. The expectant mothers attending one of the clinics (Clinic A), who had booked to be delivered in the Maternity Hospital, were given a daily supplement of ascorbic acid from the sixth month of pregnancy until the end of the sixth month after delivery—i.e., over a period of nine months covering the later months of pregnancy and almost the whole period of lactation. The supplements consisted of 50-mg. tablets of ascorbic acid, and the patient was requested to take one tablet a day for the nine-months period. The tablets were given out at the ante-natal clinic, and supplies were renewed at subsequent visits, in the Maternity Hospital, at the child welfare clinics, or delivered at the home. The dosage chosen was based on a daily requirement of 30 mg. for an adult as recommended by the Technical Commission on Nutrition (1938), but some surplus (20 mg.) was allowed owing to the increased demands of pregnancy and lactation. The total daily intake was probably in the region of 70 mg., as these women were presumably consuming some vitamin C in their ordinary diet—probably not less than 15 to 20 mg. a day—and the 50-mg. tablet was considered to be in the nature of a supplement to bring what might be an inadequate intake up to a satisfactory level. Graham and Cameron (quoted in the Departmental Report on Infant Mortality in Scotland, 1943) found that in Glasgow the average values of vitamin C in the diets of 300 pregnant women varied from 30 to 42 mg. a day.

The great disadvantage in dealing with out-patients is that it is impossible to be sure that the tablets are actually ingested. Most experiments of this nature have been carried out in hospitals, schools, and other institutions, where the subjects are under direct control and supervision, and where supplements can be added to the diet. In this experiment the difficulty could not be overcome in any way; but tests were carried out on every patient while in the Maternity Hospital to estimate the degree of saturation, and this was very helpful in assessing the previous regularity of ascorbic acid consumption.

The group of patients attending Clinic A, who received supplements of ascorbic acid, will be referred to as Group A, and consisted of 124 women. The patients attending Clinic B did not receive any supplement, and acted as controls; they numbered 126, and will be referred to as Group B. Comparisons between the two groups as regards age, parity, and income levels were made. The average age of Group A patients was 27.30 years, which was very much the same as the average for Group B—namely, 27.62. The average weekly income per household was slightly higher for the Group B patients, being 75s. 10d., as compared with 68s. 9d. for Group A. There was a greater proportion of primiparae in Group B (52.4%) than in Group A (47.6%).

On admission to the Maternity Hospital, where Group A patients continued to have a daily dose of 50 mg. of ascorbic acid, all patients in both groups were examined and particulars taken as to previous diet, with special reference to the consumption of fruit and vegetables, weekly incomes, and number of members in the household. In the case of Group A inquiries were made as to the regularity of the tablet consumption. The vitamin C nutrition of both groups was assessed by means of the saturation test devised by Harris and Abbasy (1937).

In the early part of 1943 the Maternity Hospital had to be closed owing to an outbreak of puerperal infection and, for this and other reasons, 15 women in Group A were delivered at home instead of in the hospital, as had been originally intended. Supplies of ascorbic acid tablets to these women were continued, but it was not possible to carry out saturation tests. As the Group B patients were only "enrolled" on admission to hospital all in this group were tested.

It was found that a fair number in Group A were not saturated for several days, which suggested either that the tablets had not been taken regularly or that the demands were greater than the amount of vitamin supplied.

It is considered by Harris (1943) that subjects who saturate on the second day of test-dosing have a satisfactory intake as judged by the League of Nations standard, and that with daily intakes of 50 to 75 mg. saturation will occur on the first day. On the other hand, when intakes are appreciably below the League of Nations standard, three days or more are required for saturation.

According to this standard, only one-half (50.5%) of the 109 women in Group A who were tested could be considered to have had an adequate intake prior to testing. This state of saturation of the women in Group A was judged to be not entirely satisfactory, but the degree of saturation in Group A was much better than in Group B, in which only 10 women (7.9%) were saturated by the second day. It may also be noted that, whereas 20 (18%) of Group A were unsaturated by the end of the fourth day, 87 (70%) in Group B took more than four days to reach saturation level.

The average amount of ascorbic acid required for saturation was 1,673 mg. for Group A—just a little more than half of the 3,076 mg. required for Group B. These figures may be compared with the average number of milligrammes of ascorbic acid required to saturate members of the staffs (nursing and medical) of two municipal hospitals (1,165 mg. for the staff of one hospital and 1,421 mg. for the staff of the other).

TABLE I.—*Number of Days of Test-dosing required to Attain Saturation*

Days	Group A		Group B	
1	31	55 (50·5%)	3	10 (7·9%)
2	24		7	
3	21	54 (49·5%)	19	116 (92·1%)
4	13		10	
5	12		32	
6	6		24	
7	2		22	
8	—		6	
9	—		2	
10	—		—	
11	—		—	
12	—		—	
13	—		*1	
Total	109		126	

* This patient showed no evidence of scurvy. The gums were healthy, but she was completely edentulous.

It would appear from the results of the saturation tests that pregnant women require supplements of vitamin C to bring the intake up to a satisfactory level; but Harris (1943) is careful to point out that saturation is not necessarily desirable and that "sub-standard" is not synonymous with "clinically deficient." Although many members of both groups were found to be deficient in vitamin C there was a big enough difference in the saturation levels of the two groups to allow some comparisons to be made.

Effect of Vitamin C Administration on Incidence of Mastitis

The incidence of suppurative mastitis in both groups was very high, and more than double the rate found by a notification scheme elsewhere described (Fulton, 1945). It must be remembered, however, that these patients were very carefully observed and followed up for a period extending to the end of the first six months after delivery, whereas under the notification system referred to cases may have been missed. It was impossible to complete the follow-up of five patients (four in Group A and one in Group B) who left the district before the six-months period had expired and could not be traced, and two in Group B who died. Consideration must also be given to the fact that the great majority (all but the 15 in Group A who were delivered at home) were hospital patients, and most authorities agree that patients delivered in hospital are much more prone to develop mastitis.

Table II shows that the incidence of mastitis, including cases which resolved without abscess formation, was almost equal (30% in Group A and 30.9% in Group B), but there was a slightly greater percentage of suppurative mastitis in Group A (26.7%, as compared with 23.6% in Group B). It would not have been surprising if these figures had been reversed, as Group A was more favourably situated as regards two factors considered to be predisposing causes —viz., primiparity and delivery in hospital.

TABLE II.—*Incidence of Mastitis in the Two Groups*

	Group A	Group B	Total
Mastitis (suppurative) ..	32 (26·7%)	29 (23·6%)	61 (25·1%)
„ (non-suppurative) ..	4 (3·3%)	9 (7·3%)	13 (5·3%)
No mastitis	84 (70·0%)	85 (69·1%)	169 (69·5%)
Untraced	4	3	7
Total	124	126	250
Primiparae	59 (47·6%)	66 (52·4%)	
Number confined in hospital	109 (88·0%)	126 (100·0%)	

From these results it would appear that vitamin C administration *per se* has no influence in reducing the incidence of mastitis, and this is borne out when the available information is analysed more fully.

The number of patients with mastitis in whom the state of vitamin C nutrition was estimated by means of the saturation test was 69—57 with abscess formation and 12 in whom the condition subsided.

Mastitis Cases tested by Saturation

It can be seen from Table III that the average amount of ascorbic acid required to saturate the patients with suppurative mastitis was 1,221 mg. in Group A and 3,167 mg. in Group B; the comparable figures for non-suppurative mastitis were 1,600 mg. for Group A and

3,067 mg. for Group B. These may be compared with the average amounts required to saturate all the members of each group.

Table III.—*Average Amount of Ascorbic Acid in milligrammes required for Mastitis Cases to Attain Saturation*

	Suppurative Mastitis	Non-suppurative Mastitis	Average for Whole Group
Group A ..	1,221 (28 cases)	1,600 (3 cases)	1,673 (109 cases)
Group B ..	3,167 (29 „)	3,067 (9 „)	3,076 (126 „)
Both groups ..	2,210 (57 „)	2,700 (12 „)	2,425 (235 „)

As regards the time required to attain saturation of the patients who developed mastitis, 17 (29.8%) of the suppurative cases (all in Group A) and 3 (25%) of the non-suppurative cases (two in Group A and one in Group B) were saturated by the end of the second day—i.e., they could be considered to have a satisfactory intake according to the League of Nations standard. Therefore the attainment of a satisfactory level of saturation by itself did not prevent mastitis in one-quarter of the cases (Table IV).

Table IV.—*Number of Days of Test-dosing required to Attain Saturation of Mastitis Cases*

Days	Group A		Group B		Total	
	(*a*) Suppurative Mastitis					
1	13	60·7%	0	0%	13	29·8%
2	4		0		4	
3	9	39·3%	6	100%	15	70·2%
4	1		2		3	
5	1		7		8	
6	0		6		6	
7	0		7		7	
8	0		1		1	
	28		29		57	
	(*b*) Non-suppurative Mastitis					
1	0	66·7%	0	11·1%	0	25%
2	2		1		3	
3	0	33·3%	0	88·9%	0	75%
4	1		1		2	
5	0		4		4	
6	0		1		1	
7	0		2		2	
8	0		0		0	
	3		9		12	

The incidence of suppurative mastitis in 62 patients of both groups who had reached a satisfactory level of saturation by giving a response before the third day was 27.4% (Table V).

From the results of the experiment it would appear that supplements of vitamin C, or a level of saturation denoting a satisfactory intake of this vitamin, had no beneficial effect on the incidence of mastitis.

Table V.—*Incidence of Mastitis in Patients who Reached the "Satisfactory" Standard—i.e., Response Before the Third Day*

	Group A	Group B	Total
1st and 2nd day responses ..	55	10	62
Suppurative mastitis	17	—	17 (27·4%)
Non-suppurative mastitis ..	2	1	3 (4·8%)
No mastitis	33	9	42 (67·7%)
Untraced	3	—	3
Total	55	10	65

Discussion

The results of this experiment would seem to indicate that a deficiency of vitamin C is not the factor concerned in the high incidence of mastitis. There is no doubt that a large number of the women, when admitted to the maternity hospital, showed marked deficiency as judged by saturation tests, but they did not seem to be more susceptible to mammary infections than did those showing no deficiency. It was possible to carry out the saturation tests only when the women were in hospital, and these tests were done with two objects in view; (1) to assess the degree of saturation of the women receiving supplements, in order to get some indication of the regularity of ingestion of the tablets; (2) to estimate the degree of saturation of the ordinary hospital patient who had had no vitamin C apart from what was obtained in the ordinary diet.

It is not claimed that one testing during the period under consideration would necessarily indicate the general saturation level for the whole period; the state of vitamin C nutrition may have varied—some women improving their intake after delivery, and vice versa. However, as the normal individual tends to be conservative in the matter of diet the tests probably gave a broad indication of the vitamin C nutrition of the subjects concerned. Apart from the difficulty of carrying out tests except under hospital conditions, it must be remembered that the controls—Group B, who had no supplements—entered the lactation period in a "saturated" condition as a result of the test-dosing. This was unavoidable, and it was assumed that these women would not materially change their dietary habits and would therefore soon revert to their former state of low vitamin C intake. In this connexion it is of interest to note that, in an endeavour to find out the duration of the state of "saturation" following test-dosing, some members of the hospital staff were tested at intervals of three weeks. Although, when considered over a long period, some seasonal fluctuation was noted, there was very little change from one testing to the next—e.g., a subject who in mid-December required three days of test-dosing to attain saturation required as many days in the beginning of January. It was thus reasonable to assume that the effects of saturation from test-dosing did not last longer than about three weeks.

If, however, it had been feasible to make more frequent tests and these had been carried out, the use of Group B as controls would then have given rise to a possible fallacy, in so far as these subjects could no longer have been considered to be having no supplements. As it was, the effect on the results of the experiment of Group B women entering the lactation period in a state of saturation is not likely to have been important, since the state of "saturation" following test-dosing does not appear to be of long duration. Moreover, the experiment was designed as an attempt to assess the possible part played by the administration of *supplements* of vitamin C, and Group A women, who were also saturated on the completion of the test-dosing, continued to have extra vitamin C in the form of a daily tablet containing 50 mg. of ascorbic acid. It can be argued that if vitamin C does increase resistance to infection, only in the event of the women in both groups already having such optimum intakes that they were in a state of full "saturation" and their vitamin C nutrition incapable of further improvement could additional supplies have been expected to yield no result. As test-dosing showed that this was far from being the case, Group A subjects, who had additional supplies of ascorbic acid, should have shown a lessened incidence of infection, which was not borne out by the results of the experiment.

It is apparent from the results of the saturation tests that many members of both groups, consisting of pregnant women of the type normally delivered in a maternity hospital, were deficient in vitamin C, and many, if testing had not been carried out, would normally have entered the lactational period with a gross deficiency. Judging by the average amount of ascorbic acid required to attain saturation, women in Group B showed a high degree of deficiency, while those in Group A, even with a daily supplement of 50 mg. of ascorbic acid, barely attained the level reached by institutional staffs on an ordinary diet without any supplement. Two factors may have been responsible for this deficiency: (1) greater utilization of the vitamin, due to the increased demands of pregnancy; (2) low intakes due to poverty, ignorance, or faulty methods of preparation and cooking of food.

Although many members of Group A showed some deficiency, it would be unfair to suggest that the daily supplement of ascorbic acid was necessarily insufficient, as there was no guarantee that all the women in this group actually ingested the supplements, and any defaulters in this respect would raise the apparent level of deficiency for the whole group.

In considering these negative results it must be remembered that the experiment was concerned with the intake of a single food factor. Proof of a possible relationship between mastitis and deficiency of any single dietary constituent may be difficult to obtain on account of the almost inevitable coexistence of other deficiencies. If a deficiency of one factor is present the simultaneous existence of other deficiencies is extremely likely. To increase the supply of one deficient factor without at the same time increasing the supply of the others may not be sufficient to affect the health and resistance of the subjects concerned. It is also to be remembered that the supplement used was a synthetic product, and the maximum benefit of the protective substances may be obtained only when given in the form of natural foods.

Summary

When comparing two groups of women for a period extending from the later months of pregnancy until six months after delivery, one of the groups being supplied with supplements of ascorbic acid, it was found that there was a deficiency of vitamin C, as measured by saturation tests, in both groups; the deficiency was naturally greater in the group without the supplements.

The incidence of suppurative mastitis in both groups taken as a whole was very high. When approximately 250 expectant mothers were followed up over a period of six months following delivery it was found that 25% suffered from breast abscess. It is to be noted that, with few exceptions, these patients were delivered in hospital.

There was no reduction in the incidence of mastitis in the group receiving the supplements or in those who gave evidence of a satisfactory intake as judged by saturation tests.

ACUTE IDIOPATHIC PORPHYRIA

BY

G. DISCOMBE, M.B., B.S., B.Sc.
Senior Demonstrator of Pathology

AND

JOHN L. D'SILVA, D.Sc., M.R.C.P.
Lately Chief Assistant

St. Bartholomew's Hospital

In the porphyrias uroporphyrins are excreted in the urine, in contrast with coproporphyrinuria, which occurs in many diseases. The porphyrias have been reviewed in detail by Mason *et al.* (1933), Waldenström (1937), Chandler *et al.* (1939), Roger *et al.* (1939), Dobriner and Rhoads (1940), and Nesbitt (1944).

Waldenström (1937) has described five types of acute porphyria: (*a*) Latent porphyria—an asymptomatic form in which uroporphyrin is excreted continuously or intermittently, for years, in the urine. (*b*) Abdominal type—onset sudden, with colic, vomiting, obstinate constipation, and tympanites. (*c*) Nervous type—onset sudden, with pareses of the extremities, convulsions, confusional states, coma, or bulbar paralysis. (*d*) "Classic type"—both abdominal and nervous symptoms. (*e*) Comatose type—abdominal colic, rapid onset of coma, and death.

In all types tachycardia and hypertension occur during the acute attack. In nearly all cases the urine contains uroporphyrin-III, with but traces of the series-I isomer; occasionally the latter predominates (Turner, 1938; Golden, 1943). Sometimes acute porphyria occurs during the prolonged administration of trional, tetronal, or sulphonal, and these have been regarded as "toxic" porphyrias (Mason *et al.*, 1933; Nesbitt and Watkins, 1942), but Waldenström considers that the division between toxic and idiopathic groups is very questionable.

The diagnosis is established by the demonstration of porphyrin in the urine. In some cases the freshly voided urine is normal in colour and contains porphobilinogen (Vahlquist, 1939), which changes to porphyrin on standing or heating. The presence of porphobilinogen is recognized by Watson and Schwartz's test (1941). The reddish-brown colour of the urine which contains porphyrin is due to the formation of coloured substances such as urofuscin, urorosein, and indirubin from colourless chromogens (cf. Turner, 1938; Watson, 1939).

The porphyrin may be present as a zinc complex (Turner, 1938; Chandler *et al.*, 1939; Nesbitt and Watkins, 1942) which has absorption bands indistinguishable in position, if a hand spectroscope only is used, from those of oxyhaemoglobin—differing, however, in that the β band is more intense than the α band, whereas in oxyhaemoglobin the reverse is true.

A few cases have been reported (Backer-Gröndahl, 1935; Schie, 1939) in which the symptoms closely resembled those of the "abdominal type" of the disease but the dark-coloured urine contained no detectable traces of porphyrin. Waldenström (1939) described a similar case, but during a remission of the disease the patient excreted pathological amounts of porphyrin.

The case described below is put on record for three reasons: (*a*) it was under continuous observation for two years, during which four exacerbations of the disease occurred; (*b*) in one of these the porphyrin output was followed quantitatively from day to day; and (*c*) in several relapses the clinical picture varied.

Case History

The patient, a sheet-metal worker aged 19, was admitted to St. Bart's for investigation on April 4, 1942. He was quite well until June, 1941, when he had a fairly sudden onset of dull aching pain round and below the umbilicus. This soon became colicky in nature and severe, but the pain did not radiate. Attacks lasted for two or three hours and had no relation to food or exercise. Nausea, vomiting, and obstinate constipation were prominent features of the illness. Some two weeks later he had five "fits" in one morning and was admitted to a hospital with a *Bact. coli* infection of the urine and a B.P. 150/110 but no other abnormal signs. The urine was free from lead, and the C.S.F. and a radiograph after a barium enema were normal. The urinary infection cleared satisfactorily, the B.P. returned to normal, and he was discharged in three weeks.

Second Attack.—In Jan., 1942, he was readmitted to hospital with symptoms similar to those in the first attack. The urine was reported as normal, but the colicky pains persisted for a few days. B.P. 160/100. He was discharged within three weeks.

Third Attack.—On March 28, 1942, he complained of aching in the limbs followed by colicky abdominal pain, vomiting on one occasion, and obstinate constipation. On April 4 he was admitted to this hospital for investigation, when, in addition to the above history, he reported having lost a considerable amount of weight during the past six months. On examination the fauces were injected, there was slight tachycardia (pulse 90), and the B.P. was 160/120. There was slight tenderness in the abdomen below the umbilicus and the liver margin was just palpable. The urine was dark brown in colour, of sp. gr. 1032, without protein, ketone bodies, or blood. It reduced Benedict's reagent, and Schlesinger's test for urobilinogen was strongly positive. Examination of the fresh urine with the direct-vision spectroscope showed no abnormal absorption bands, but on standing for some hours it darkened and the two-banded spectrum of porphyrin became visible in a half-inch layer. An amyl alcoholic extract of the fresh or of the stale urine showed the α, β, and γ bands of alkaline porphyrin, converted by hydrochloric acid to acid porphyrin. Toluene-soluble red pigments were also present.

Investigations.—Hb, 118%; R.B.C., 5.5 millions; W.B.C., 6,800, with a normal differential count. There was no punctate basophilia. E.S.R., 1 mm. in the first hour. Serum bilirubin was normal. Blood W.R. and Kahn tests were negative. The reducing substance in the urine was proved to be glucose. A glucose-tolerance curve gave the following result (blood sugar in mg. per 100 c.cm. followed by time in hours, in parenthesis, after the test dose of glucose): 88 (0); 148 (1/2); 140 (1); 125 (1½); 115 (2). Urine specimens before the test dose and two hours afterwards contained sugar, which indicates a low renal threshold for glucose. Radiographs of the lungs, abdomen, and kidneys were normal. The skull was normal except for a small pituitary fossa (transverse, 8 mm.; vertical, 3 mm.; and interclinoid measurement, 1 mm.).

Course of the Illness

Nausea and constipation were marked, but abdominal pain did not amount to more than discomfort below the umbilicus. The patient lost weight very rapidly, as shown by Fig. 1; and on April 28 (fourth week after admission) he had an epileptiform attack associated with cyanosis and widespread clonic movements but no incontinence. B.P. remained about 150/110, and tachycardia persisted. By the sixth week increasing weakness of the large muscle groups of his arms and legs was apparent, and there was fibrillary twitching in the deltoid and pectoral muscles. Reflexes were absent in both arms, and pain sensation was blunted on the trunk and face. Within two weeks he became so weak as to be unable to move his hands or arms, and his voice was very hoarse and feeble. There was gross wasting of all muscle groups in the arms, forearms, and hands; fibrillary twitching had ceased. He had difficulty in standing because of weakness of the legs. Knee- and ankle-jerks were present and equal, with the plantar responses Babinski-negative. He sustained a burn from a hot-water bottle on his leg, and it was found that sensitivity to pinprick was impaired in both legs (it had been normal a week earlier), but position sense was normal. For a period of six weeks he was unable to feed himself. By the tenth week his voice was stronger, his weight was increasing, and there was some return of power to the flexor muscles of the arms. Six weeks later there was still gross wasting of the pectorals and deltoids, biceps and triceps groups, forearm muscles, especially the ulnar group, and of the intrinsic muscles of the hands. The arms could not be abducted. Full flexion and extension of the elbows were possible, but without power. There was bilateral wrist-drop. Touch, vibration, and position sense were normal, but there was blunting of pinprick sensation, especially on the hands, and the tendon reflexes were absent. Abdominal reflexes were absent. The muscles of the legs were of good tone and there was no wasting. All leg movements were weak but incomparably stronger than those of the arms. Tendon reflexes were normal.

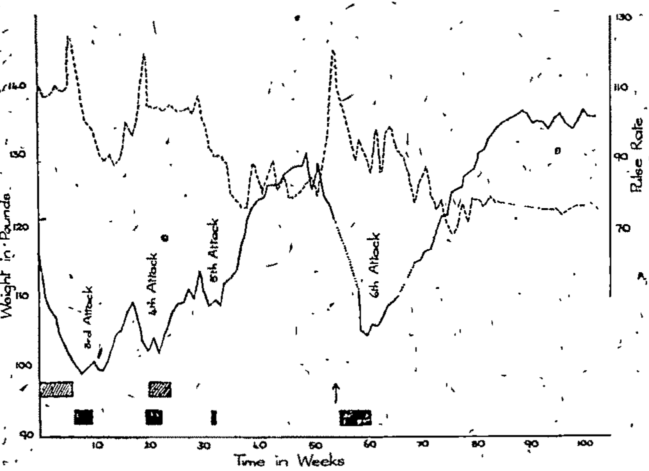

FIG. 1.—Weekly variations in the patient's weight: ——. Average weekly pulse rate: - - - - -. No observations made: . . . . . . Black rectangles: Duration of abdominal symptoms. Shaded rectangles: Time during which barbiturates were given. The arrow: Sulphathiazole given.

Fourth Attack.—From the 20th to 22nd weeks he complained of much abdominal pain and was constipated. His weight decreased considerably (Fig. 1), but there was no extension of paralysis. By the 30th week his legs were normal, but his arms were still grossly wasted and weak, without tendon reflexes yet with enough power slightly to abduct the arms and dorsiflex the wrists. Sensation in the arms was normal, but there were no abdominal reflexes. Within two weeks marked improvement was apparent. The arms could be moved relatively easily and all the tendon and abdominal reflexes had returned.

Fifth Attack.—During the 32nd week he again complained of slight abdominal pain and constipation and, though this was associated with loss of weight, there was no extension of paralysis. From this time there was gradual but continued recovery of muscular power and the wasted muscles regained their normal contours. By the 52nd week the patient was able to help in the ward and could support the weight of a laden tray and perform fine movements with his fingers.

Sixth Attack.—On April 16, 1943 (54th week), a small pustule appeared on the ring-finger of the right hand and lymphangitis developed next day. Sulphathiazole was started, but was discontinued after 9 g. had been given. On April 21 he vomited and experienced severe abdominal colic, and his limbs felt very heavy. He had been losing weight for four weeks. The only abnormal signs were tachycardia and a B.P. of 160/130. During the succeeding week he suffered from marked insomnia and was at times mentally confused. The power of his shoulder-girdle muscles diminished rapidly and in 10 days he was practically unable to move his arms. Simultaneously, the muscles wasted rapidly and there was a further marked loss of weight. The distribution of the weakness and wasting was as in the third attack, but in addition he had tenderness of both quadriceps and knee-jerks were absent. At this time there was no hepatic involvement as judged by the bromsulphthalein dye excretion test. The legs soon recovered their normal power, but even after three months—long after the abdominal and mental symptoms had disappeared—there was gross weakness and wasting of both arms (the right more than the left), abduction being very poor. By the 73rd week movements of the large joints of the arms were good and reasonably strong. The dorsal interossei of the hands, especially the first, were still very weak and wasted, and the power of the lumbricals was poor. Eighty-seven weeks after admission the small muscles of the hands had recovered to a considerable extent—enough to enable him to weave. Improvement continued until his discharge on April 8, 1944, when his weight was steady. He was then working at occupational therapy for several hours a day and could write without difficulty. His urine still contained considerable amounts of porphyrin and of urobilin.

Five months after his discharge the patient was working as a clerk for six hours a day; weight 138 lb., pulse 72, B.P. 124/72. His urine contained a great deal of porphobilinogen and urobilinogen, and yielded much porphyrin and moderate amounts of the associated red pigments on standing. At this time a single specimen of the urine of each of his parents was examined, but neither contained porphyrin.

Comment

Fig. 1 records the patient's weight and pulse rate throughout his stay in hospital—that is, from soon after the start of his third illness until his discharge. The gross loss of weight which preceded each relapse is well shown, as was the recovery of weight when the symptoms subsided. The fourth and fifth attacks, which were minor episodes clinically, were also associated with a definite fall in weight. The greater loss of weight associated with the sixth attack was in keeping with the fact that it was comparable in severity with the third illness. Each point on the pulse-rate curve represents the average reading for the week. Tachycardia was a marked feature of the condition, with peaks in the curve of pulse rate corresponding to each relapse. The black rectangles indicate the duration of abdominal symptoms—namely, pain alone, or with vomiting and nausea. The shaded rectangles denote the duration of administration of phenobarbitone. The arrow represents the point at which sulphathiazole was given.

Excretion of Porphyrins.—Prof. C. Rimington kindly investigated quantitatively the output of porphyrins in the urine by methods which he has published elsewhere (1943). He found that uroporphyrin-III predominated in the urine, the isolation of which as its octamethyl ester completed the clinical diag-

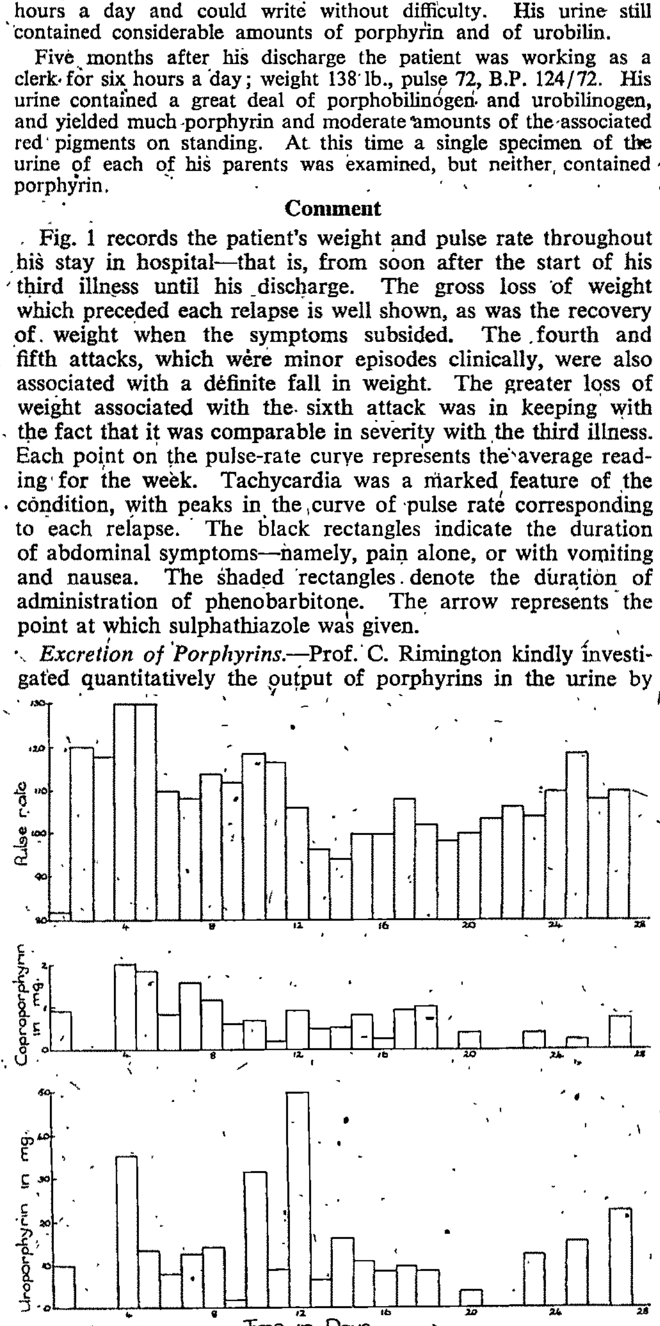

FIG. 2.—Lowest chart: Day-to-day excretion of uroporphyrin in mg. during the fourth attack (cf. Fig. 1). Middle chart: Corresponding excretions of coproporphyrin in the urine. Upper chart: Daily variations in pulse rate.

nosis. Coproporphyrin-III and a very small amount of coproporphyrin-I were also found. Fig. 2 represents the day-to-day excretion of uroporphyrin and of coproporphyrin from the 19th to the 23rd week after admission. The daily variations in pulse rate are also charted. An increase in porphyrin excretion was associated with a rise in pulse rate, though the correspondence was not exact.

Conclusion

The administration of sulphonamides or of barbiturates may precipitate an attack (Mason *et al.*, 1933; Waldenström, 1939; Nesbitt and Watkins, 1942). Phenobarbitone, 1 gr. twice daily, was given for periods of several weeks during the third and fourth attacks, but there was no evidence that the drug affected their course adversely. The onset of the sixth relapse cannot be attributed to the administration of sulphathiazole, as the patient had then been losing weight for about four weeks—a sign, in his case, of pending relapse. A noteworthy feature of the disease is the degree of restoration of function of the paralysed muscles, which in this patient appeared nearly complete.

Summary

A patient complaining of attacks of abdominal pain, constipation, and fits was found to be excreting uroporphyrin-III in his urine and to be suffering from acute porphyria. A marked decrease in body weight preceded the onset of symptoms.

In the course of three years he experienced six relapses, in each of which the symptomatology varied. Recovery now appears to be complete although porphyrinuria persists.

In one attack the daily variation in porphyrin excretion was determined.

The clinical features of the disease and methods by which the diagnosis may be confirmed in the laboratory are described.

We wish to thank Dr. Geoffrey Evans for permission to publish this case.

SIMMONDS'S DISEASE DUE TO POST-PARTUM NECROSIS OF THE ANTERIOR PITUITARY: CARCINOMA OF STOMACH

BY

R. T. COOKE, M.D.

Assistant Pathologist, Preston Royal Infirmary

Although the papers by Sheehan (1938, 1939, 1940) and Sheehan and Murdoch (1938, 1939) have clarified knowledge as to the causation of Simmonds's disease and stimulated interest in this condition, descriptions of cases due to necrosis of the anterior pituitary lobe resulting from post-partum collapse are still rarely seen in the clinical journals. The following case may therefore be of interest. It is reported alone, although other presumptive cases have been seen in this department during the past few years, including that of a woman who had amenorrhoea dating from the birth of her last child when she was 30, and who died, aged 39, of carcinoma of the bladder, with an extensive neoplastic spread in the pelvis. Post-mortem examination revealed splanchnomicria and (both to the naked eye and in serial sections) the typical atrophy in the anterior pituitary. Owing to her general condition, however, few investigations had been done during life.

Case Report

Mrs. W., aged 59, was referred for investigation on Feb. 23, 1943, by Dr. F. M. Rose, of Preston. She gave a history of progressive tiredness and loss of 1 st. in weight over the past year, and anorexia and numbness of the fingers since an attack of influenza in 1942. She had mentioned epigastric pain to her doctor, but told me that there had been no pain, vomiting, epistaxis, or dysphagia. She had had four pregnancies; her son was aged 37, the middle two children had died at 11 months and 2 years old, and her daughter was 27. The first three confinements were uncomplicated, but at the birth of the last child, when the patient was 32, there was severe haemorrhage and she was in bed seven weeks or more from weakness. She menstruated 5 months later, and again, for the last time, four months after that. After the delivery she did not lactate, and the breasts, from being large, became very small. Loss of hair was soon noticed (especially axillary and pubic), and she gained 1½ st. in weight. A year passed before she regained her strength. Sensitivity to cold developed, becoming more pronounced during the last year. No change in sex feelings could be recalled. The patient's daughter-in-law said that she had been pale for 15 years or more, but the pallor had become more grey over the past year, and the cheeks were sunken. No psychological changes had been noted, such as peevishness, unkindness, absentmindedness, faints, fugues, or attacks of coma.

Examination.—Height, 5 ft. 1 in.; weight, 6 st. 11 lb. The pallor and wasting gave the clinical picture of cachexia; face wrinkled, cheeks sunken, no glossitis; axillary and pubic hair absent; scalp hair thin; eyebrows very thin; breasts flat and atrophic; soft quick pulse, with occasional dropped beats (B.P. 100/60); oedema of lower legs; nothing abnormal felt in abdomen. Physical examination otherwise negative.

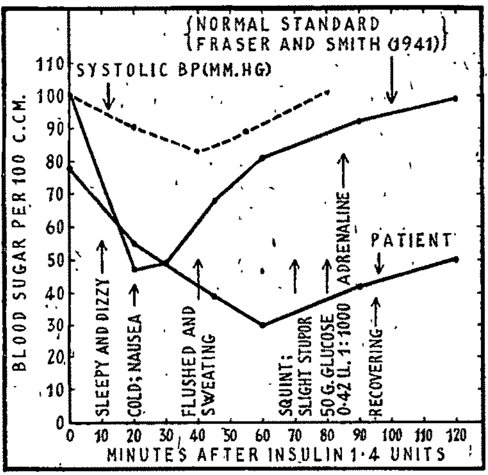
Progress.—Feb. 23: Urine normal. Feb. 25: B.M.R., –9%. Fractional test meal: Histamine-fast achlorhydria without evidence of stagnation or organic lesion. March 9: Glucose-tolerance test—normal curve; electrocardiograph, "T_3 inverted" (Dr. Harold Isaacson). March 12: B.M.R., –37%. March 24: Insulin sensitivity test (Fraser and Smith, 1941). As there were clinical grounds for suspecting pituitary insufficiency, one-third of the standard dose of insulin was used—i.e., 0.1 unit per 3 kg. of body weight. After 1.4 units of insulin had been given intravenously the blood sugar fell from fasting level of 78 mg. per 100 c.cm. to 38 mg. per 100 c.cm. in 45 minutes and 30 mg. per 100 c.cm. in 60 minutes. In the healthy subject symptoms of hypoglycaemia should not persist after this one-hour point. As the patient then showed slight clouding of consciousness and a slight squint, the test was cut short by 50 g. of glucose orally, and an intramuscular injection of 0.42 c.cm. of 1: 1000 adrenaline. The lowest figure for the systolic blood pressure was 82 mm. Hg 40 minutes after the insulin. She was admitted to hospital for a rest and was discharged two days later feeling no ill effects.

[The following explanation of the insulin sensitivity test is quoted from Fraser and Smith (1941): "The rate of the initial fall in the blood sugar differentiates normal or increased insulin sensitivity from insulin resistance; and the speed of the subsequent return to the fasting level will indicate any tendency to persistence of hypoglycaemia—that is, a delay in return will indicate 'hypoglycaemia unresponsiveness,' which may be found mainly in hyperinsulinism, hypo-adrenocortinism, or panhypopituitarism. Thus the characteristic result of this test in panhypopituitarism is a normal rate of fall associated with an abnormally slow return to the fasting level, or 'hypoglycaemia unresponsiveness'."]

The accompanying Graph shows the slow and prolonged fall of the patient's blood sugar and the typical delayed rise. Fraser and Smith's "index of hypoglycaemia unresponsiveness" is 320 (normal 550 ± 70). The result of this test, therefore, was further evidence for the presence of a lesion in the anterior hypophysis.

May 1.—Urinary 17-ketosteroid assay (Fraser and Smith, 1941): result—zero figure in 24-hour sample of urine, using Callow and others' (1939) modification of the method of Dingemanse, Borchardt, and Laqueur (normal value for women, 1.7 to 12.6 mg. in 24 hours). After attending for a blood count on April 2, Mrs. W. was unable to report here again. She received no specific treatment and slowly weakened. She died on Oct. 6, 1943, of cachexia and heart failure.



Necropsy (Oct. 6, 1943).—Dryness and desquamation of the skin, oedema of legs; moderate amount of clear fluid in pleural and pericardial sacs; very small thyroid (6.5 g.); thymus not seen; small heart (150 g.); fibrosis at apex of left lung (right 380 g., left 240 g.); thin intestinal wall; small liver (650 g.); spleen, 65 g.; cancerous ulcer in pyloric antrum of stomach 1 in. across and puckering the peritoneum; no metastases or neoplastic glands; adrenals atrophic—combined weight 5 g., cortices very thin, medullae not obvious; kidneys 85 and 100 g., capsules strip smoothly, fine cortical cysts, cortices slightly narrow; tiny uterus (25 g.) and ovaries (3 g. the pair). The base of the brain was hardened *in situ* by formalin in the skull overnight. The pituitary, when removed still attached to the brain, appeared as a collapsed empty shell.

Histology.—Thyroid: Increase of fibrosis. Adrenals: Partial atrophy. Uterus: Atrophy of endometrium and myometrium. Ovaries: Atrophy. Left lung apex: Fibrosis; anthracosis. Liver: Fat ++ ; variable size of cells and nuclei. Kidneys: Exudate in glomerular spaces; some tubular debris. Spleen: Follicular fibrosis. Pyloric ulcer: Adenocarcinoma. The pituitary was not sectioned; the base of the brain, with attached hypophysis, was given to the Royal College of Surgeons.

Summary

A case of Simmonds's disease is described in a woman aged 59, due to necrosis of the anterior pituitary dating from a confinement 27 years before.

Attention to the obstetrical history makes the presumptive diagnosis simple in this condition.

Among other clinical pathological tests the results of the insulin sensitivity test and the urine 17-ketosteroid assay added weight to the diagnosis.

Necropsy revealed a general splanchnomicria as expected, but also an "early" pyloric carcinoma which was not expected. Was this a coincidence, or was it another result of the pituitary lesion?

I am grateful to Drs. F. M. Rose and F. B. Smith for their co-operation and permission to publish, and to Mr. G. E. Delory, M.Sc., for help with the biochemical tests. I wish also to thank Lieut.-Col. H. L. Sheehan for much interesting advice and correspondence.

J. D. Durance (*J. R.A.M.C.*, 1945, **84**, 280) maintains that, though there are other causes of subconjunctival petechiae, it is safe to treat as positive all cases of pyrexia or mental disturbance exhibiting these signs on the first day of the disease during an outbreak of cerebrospinal fever, and begin chemotherapy immediately. The absence of subconjunctival petechiae is a good prognostic sign.

HAEMOLYTIC DISEASE AND CONGENITAL SYPHILIS IN SIBLINGS

THE ROLE OF THE Rh. FACTOR

BY

MARJORY N. McFARLANE, M.B., Ch.B.

(From the Departments of Pathology of the University of St. Andrews and Dundee Royal Infirmary)

It has been alleged that congenital syphilis may give rise to a clinical picture identical with erythroblastosis (Holt and McIntosh, 1933). A history of neonatal jaundice, foetal dropsy, or intra-uterine death in successive pregnancies has been regarded in the past as confirming the diagnosis of syphilis. On this supposition, even in the absence of serological and histological evidence of the disease, women with such unfortunate obstetric histories have been subjected to prolonged courses of antisyphilitic treatment. Syphilis and erythroblastosis foetalis (or haemolytic disease of the newborn, as it is now called—Parsons, 1943) resemble each other in that each may cause the repetition of obstetric disasters; but the obstetric histories differ characteristically in the two conditions, the earlier children usually being spared in haemolytic disease but dying in syphilis. Levine *et al.* (1941) discovered that the chief cause of haemolytic disease lies in iso-immunization of the mother to the blood-group factor Rh, present in the foetal cells and absent from her own. Tests for the Rh factor are thus of value in differential diagnosis, and provide a criterion by which the importance of syphilis, umbilical sepsis, or other alleged cause of erythroblastaemia may be assessed. Since the discovery of the possible results of blood-group incompatibility between mother and foetus the formerly alleged causes of erythroblastosis can no longer be accepted until it has been clearly proved that there is no evidence of, or basis for, iso-immunization. There does not appear to be any published example of erythroblastosis in a newborn syphilitic infant in which a concurrent Rh incompatibility between the mother and child has been excluded. Henderson and Macgregor (1943) reported a case of hydrops foetalis (haemolytic disease Type I) in the child of a syphilitic primigravida with anti-Rh agglutinin in her serum and with unequivocal histological evidence of erythroblastosis in the foetal tissues. This case supports the new concept that the foetal condition was attributable to the Rh incompatibility rather than to the syphilis.

I have recently observed a family in which haemolytic disease and congenital syphilis have appeared in siblings. This family illustrates well the value of tests for the Rh factor in confirming the diagnosis of haemolytic disease in the presence of maternal syphilis.

Case Notes

Mrs. C., aged 34. Group A_1 Rh-negative (rr). Husband overseas. Obstetric history: (1) 1935: female, premature, alive, Group A_1 Rh-positive. (2) 1939: male, full-time, died of icterus gravis neonatorum (haemolytic disease Type II). (3) 1941: six-months miscarriage. (4) Female, full-time, alive, Group O Rh-negative.

In 1939 the patient gave birth to a full-time male child who became jaundiced some hours after birth and died two days later. This infant was put to the breast, and on account of jaundice and petechiae in the skin he was given an intramuscular injection of 18 c.cm. of maternal blood. During this pregnancy the diagnosis of maternal syphilis had been made, and the mother continued to receive antisyphilitic treatment more or less regularly from that time until early in the fourth pregnancy. Post-mortem examination of the second infant revealed widespread erythroblastosis of the organs with abundant extramedullary haemopoiesis, the appearances being characteristic of haemolytic disease Type II. Histological evidence of syphilis was entirely lacking in all the organs and tissues.

In 1942, in the course of a study on haemolytic disease of the newborn, this patient's blood was first examined for the Rh factor and found to be Rh-negative. It was then disclosed that she had had a miscarriage about 20 months previously, and, in spite of the lapse of time since her last pregnancy, powerful anti-Rh agglutinins were present in her serum (titre 1/128).

In 1944, during the fourth pregnancy, the maternal serum was tested repeatedly from the fourth month onwards, from which time the patient remained under observation in hospital on account of her cardiac condition. The Wassermann reaction was positive, and the serum contained anti-Rh agglutinin type anti-Rh_1 (i.e., rho and rho_1) throughout the remainder of the pregnancy (titre 1/128).

In view of the previous occurrence of haemolytic disease in this family preparations were made to give the fourth baby a transfusion of Rh-negative blood immediately after birth if its cells were shown to be Rh-positive or agglutinable by the irregular antibody in the maternal serum. The fourth child, a female weighing 8 lb. 10 oz., was born spontaneously at term; tests on the cord blood within an hour of birth showed that this baby was Rh-negative and that its cells were not agglutinated by the mother's serum. The cord blood gave a positive Wassermann reaction, its haemoglobin content was 140%, and there was no erythroblastaemia. As the maternal and foetal bloods were compatible as regards the Rh factor, blood transfusion was not given and signs of haemolytic disease never developed.

Comment

This family provides a valuable commentary on the supposition that congenital syphilis may cause erythroblastosis. In the second child erythroblastosis was present, but naked-eye and histological evidence of syphilis was lacking. The presence of powerful anti-Rh agglutinins is proof that iso-immunization to the Rh factor had occurred and may reasonably be supposed to have been responsible for the foetal haemolytic disease and possibly for the subsequent miscarriage. The outcome of the fourth pregnancy, however, shows conclusively that serological evidence of syphilis in the mother and infant may be present without foetal erythroblastosis, even in a family in which haemolytic disease has previously appeared. Haemolytic disease did not develop in this child, in spite of the powerful anti-Rh agglutinins in the mother's blood, owing to the lack of the Rh-positive antigen in the foetal cells. From the persistently positive Wassermann reaction it may be inferred that syphilis was not eradicated from the mother, and time will show whether the infant develops signs of congenital syphilis other than the positive Wassermann reaction. There is at present no satisfactory evidence to show that congenital syphilis or other infection can bring about, by itself, the clinical and pathological features of erythroblastosis foetalis, and blood-group incompatibility is the only proved cause of this neonatal disorder.

GLANDULAR FEVER WITH NEUTROPENIA

BY

GERALD SLOT, M.D.
Lieut.-Col., R.A.M.C.; Officer i/c Medical Division

AND

F. D. HART, M.D.
Major, R.A.M.C.; Medical Specialist

Lieut.-Col. Shirley Smith and Major Trevor Shaw in their valuable article in the *British Medical Journal* of April 28, 1945, on treatment of anginous forms of glandular fever with intravenous arsenic, stress the fact that neutropenia is present in many cases. In the series they quote, only two cases have a marked neutropenia; the others can be considered low normals. The case reported below shows an even higher degree of neutropenia than any referred to in their paper. Like them, owing to exigencies of oversea service, we have not had full access to literature, but neither of us remembers neutropenia of a marked degree associated with glandular fever; nor is it mentioned in any of the standard works on medicine or haematology we have consulted.

Case History

Lieut. A., aged 27. Previous history: malaria, 1943 (type uncertain; ? B.T.). The patient was admitted to a military hospital, C.M.F., with the diagnosis of "loose body in left knee-joint." After a period at a convalescent depot, Major Bickerton operated on March 3, 1945. That evening, while on routine sulphathiazole by mouth, Lieut. A.'s temperature rose and continued to swing from 97° to 104.4°. His only complaint was tightness of the throat. Many blood slides were negative for malaria. Quinine (10 gr. t.d.s. for 3 days) had no effect on the fever. A few crepitations appeared at the right base. Sulphathiazole was discontinued on March 8 (total 30 g.). On March 13 he complained of a sore throat, and both tonsils were found to be enlarged, with a follicular exudate. Enlarged glands, not tender on palpation, were present in both axillae and the right side of the neck. The spleen became palpable (one fingerbreadth) in the next few days, but was never tender. By March 19 the fever began to abate by lysis. Crepitations were present over both bases. No exudate was now found on the tonsils. Painless enlarged glands, never tender to palpation, were present in groins, axillae, right side of neck, supracondylar regions along the brachial arteries, and just posterior to the right nipple. His only complaints at this time were of slight tenderness over the roots of both canines and tingling of a throbbing nature in the fingers, in the ulnar distribution, which disappeared as the glands subsided, but could be reproduced by pressure over the still slightly enlarged glands above the elbow. On March 22 temperature was normal. Since then the glandular enlargement has disappeared, but the spleen even now (June 5) is still palpable half a fingerbreadth on full inspiration, and up to three weeks before that date the moist sounds persisted in both lower lobes. As the neutropenia first noted on April 2 persisted, the effect of pentide was tried on April 15. Three injections of 10 c.cm. I.M. caused fever, shivering, flushes, nausea, and splenic contraction. Blood slides were negative, and the symptoms were without doubt directly attributable to the injections, as he noticed them after every injection, becoming more marked each time. Injections of adrenaline failed to cause splenic contraction or alteration in the blood picture.

Investigations.—(1) White blood cells (see Table). Hb 80% (Haldane) on April 6. (2) Blood slides × 12—negative for malaria parasites. (3) Blood culture—negative after 14 days. (4) Paul-Bunnell (Stitt's technique) on March 20—negative; April 13—sheep cells agglutinated to 1/128. (5) Agglutinations to *B. proteus* OX 2 and OX 19—negative. (6) Kahn—negative. (7) Formol-gel—negative.

Of interest is the persistent neutropenia since April 2, apart from the immediate effect of 30 c.cm. pentide I.M. The patient was perfectly well and making a normal convalescence all this time, and throat and mouth were normal. Crepitations were so persistent at both bases that atypical pneumonia was suspected, but two skiagrams of the chest were normal. The persistence of splenic enlargement is not unusual in these cases; in this instance it will be of interest to see if the blood count returns to normal at the same time as the spleen.

It is thought sulphathiazole therapy played no part in the production of any of his signs, as he had had only a few doses at the time of operation, which was also the time of onset of his fever. Nevertheless, neutropenia, splenomegaly, and glandular enlargement are known to occur as toxic reactions in sulphonamide therapy, and it is just possible that the drug alters the body's response to the infection of glandular fever. The whole course of the disease, however, and the persistence of the neutropenia are against a drug intoxication.

Comment

Sulphathiazole, given as a routine in clean knee cases as pre-operative preparation, was discontinued 5 days before the onset of throat symptoms. The neutropenia was not permanently affected. The effect obtained by injections of pentide lasted only 36 hours. Moist sounds occurred in the chest—a feature we have noted in other cases of glandular fever. They are similar to those heard in atypical pneumonia, except that they are bilateral. These signs persisted for some weeks. The spleen is still palpable, about half a fingerbreadth below the costal margin, 3 months after the onset of the disease, though the patient is now completely symptomless and has been so for seven weeks.

We should like to emphasize the association of persistent neutropenia and splenomegaly with infectious mononucleosis.

Medical Memoranda

Paratyphoid Ulcer of Rectum

The following case is noteworthy from the point of view of the differential diagnosis of diseases of the rectum and because of the rarity of its occurrence.

History of Case

On June 27, 1944, a sergeant air gunner, aged 21, was admitted from sick quarters to an R.A.F. hospital as a case of neoplasm of the rectum. On rectal examination the unit medical officer had felt a "mass." The patient gave a history of constipation for 7 days while on leave. On return to his unit he passed blood and mucus per rectum. He did not feel well, but he had no pain. He stated that he had lost weight and that his relatives told him while on leave that he looked much thinner.

On examination the abdomen was slightly distended and resonant. There was no tenderness or rigidity, and the liver and spleen did not appear to be enlarged. Per rectum a friable adherent mass was felt on the left side. The ulcer had a raised irregular edge, and blood was present on the examining finger. No unusual enlargement of inguinal nodes was felt. Heart and lungs were normal. The oral temperature was 100.4° F. and pulse rate 80. Next day proctoscopy revealed an ulcer the size of a half-crown on the left side of the rectum. It was oozing blood. A piece of the wall was excised for examination, but previously a swab of the base of the ulcer was taken for culture. Sigmoidoscopy revealed no other site of ulceration, and merely a congested mucosa.

Further investigations included the following: June 28: haemoglobin, 80%; haematocrit, 44%; W.B.C., 8,200 per c.mm. (neutrophils 60%, lymphocytes 37%, monocytes 3%). June 29: Chest skiagram—"Lung fields clear." June 30: Kahn negative. Also on June 30 the report on the swab of the ulcer was: "Organisms morphologically, culturally, and serologically resembling *B. paratyphosus* B isolated." The result was communicated to Air Commodore Morton, who was examining the biopsy specimen.

The patient was transferred to the medical division, and his further progress was that of a typical case of paratyphoid B infection, with serum agglutinins showing a rising titre of paratyphoid B. He made a good recovery, and on discharge Squad. Ldr. Petch (Medical Specialist) made the following comment: "A case of paratyphoid B presenting with an ulcer in the rectum. He was extremely ill for this infection, but has made a good recovery. Inoculation state as judged by records in pay-book should have afforded protection."

Squad. Ldr., R.A.F.V.R.

Foetal Erythroblastosis and Hydrops in Twins

The occurrence of a case of hydrops and erythroblastosis in twins born to a primipara presents some unusual features. Comment on the cause of the condition and the chance of a normal baby in a future pregnancy will be welcomed.

Case Report

Mrs. X., a primipara aged 24—last menstrual period Sept. 23, 1944—when first seen on Jan. 10, 1945, had slight swelling of the right ankle, which she said had been quite common even before pregnancy. She had been treated for a threatened abortion in December, and was considered to be due in May. Her blood pressure was normal at frequent examinations, but the swelling of the right ankle increased. Her Wassermann reaction was negative. In March both legs became swollen, and she complained of giddiness and dyspnoea. B.P. 110/76. A specialist reported her cardiac condition to be normal. There was some hydramnios. In April she was advised to stay in bed. On May 2 she was admitted to the infirmary in labour, with oedema of the legs and feet and albuminuria. B.P. 138/100. After a short labour she was delivered of a male infant, weighing 7 lb. 3 oz., who was grossly oedematous; the heart beat for a few minutes, but he never breathed. The second twin—a male weighing 3 lb. 10 oz.—was delivered 20 minutes later; he was oedematous over one shoulder and the side of the neck. He lived a few days. A large single oedematous placenta was expelled.

Mrs. X.'s blood count was: Hb, 72%; red cells, 3,752,000 per c.mm.; colour index, 0.96; leucocytes, 10,000 per c.mm. (polymorphs 82%, lymphocytes 16%, eosinophils 2%). The red cells were a little irregular—no reticulocytes. No abnormal white cells were seen. The Wassermann and Kahn reactions were negative. Blood urea: 20 mg. per 100 c.cm. Blood bicarbonate: 61.3 c.cm. CO_2 bound by 100 c.cm. plasma at N.T.P. Blood group: O (IV Moss) Rh-positive. There did not appear to be any irregular agglutinins in her serum.

Mr. X.'s blood group was A (II Moss) Rh-positive. His cells are agglutinated by Mrs. X.'s serum only to a titre of 1 in 32, so that a high anti-A titre is not the explanation of the case. Wassermann and Kahn reactions, negative.

Mrs. X. left the infirmary in 18 days with a normal blood pressure and no oedema. There was a faint trace of albumin in the urine. Urea, 1.03%. No blood pus or casts were found.

Post-mortem Report on Baby X.—There is general oedema of the whole body and serous membranes. Lungs: Complete atelectasis. Heart: The foramen ovale is very large. Liver: Very small and tough, with a large haemangioma on the surface. Spleen, small. Kidneys and suprarenals appear normal.

Report on Sections Taken at Time of Necropsy.—Kidneys absolutely normal, with nothing pathological in them. The suprarenals are also quite normal. The spleen is extremely congested, and there are no lymphoid follicles; it seems to consist entirely of reticulo-endothelial cells, and the vessel walls are very fibrous and thick. The liver is very congested, with a great quantity of blood pigment in it. There is a large amount of round-cell infiltration, and Glisson's capsules are extremely fibrotic, but apart from this there does not seem to be much fibrosis. The lungs show complete atelectasis.

The second baby was sent to a voluntary hospital as it was becoming more oedematous; it died there after a few days. A blood count showed: Hb, 163%; R.B.C., 7,100,000 per c.mm.; colour index, 1.15; leucocytes, 53,400 per c.mm. (polymorphs 20%, lymphocytes 70%, monocytes 10%). Though the stained film showed tremendous numbers of nucleated red cells, while counting a hundred white cells 1,010 nucleated red cells were seen. No necropsy was performed.

My grateful thanks are due to Dr. Mackarell, pathologist, and to Dr. O'Donovan for reports and helpful advice in this case.

Nuneaton. Eileen Malone, L.R.C.P.&S.I.

A Case of Volvulus of Small Intestine

The following case may be of interest to readers by reason of its comparative rarity and because of the difficulty of early diagnosis.

Case Notes

The patient was an Army officer aged 34. He had had an appendicectomy (two scars), and had suffered from "heartburn" off and on for years. On admission on July 25, 1944, he complained of very severe pain in the mid-abdomen since 1 a.m. and had vomited bile-stained fluid. Pulse 74, temperature normal; rigidity and tenderness of both rectus abdominis muscles, the right more so than the left; no distension apparent. He was very ill and, although he did not present a typical picture of a perforated duodenal ulcer, it was thought wise to "look and see," after consultation with the medical specialist.

Operation (1).—Upper right paramedian incision. Nothing abnormal discovered (no perforated duodenal ulcer and no obstruction; gall-bladder normal). After further intermittent attacks of pain and vomiting bile, he eventually became acutely obstructed and very ill. Enemata yielded no result. Distension very marked.

Operation (2).—Abdomen opened on July 28 by a lower right paramedian incision of ample length. Obstructed distended coils of gut presented, and were traced to the now complete volvulus of small intestine near the base of the mesentery on the right side, by the sacro-iliac synchondrosis. The purple loop was untwisted, and soon recovered its colour and sheen on bathing with hot saline. The abdomen was then closed without drainage.

He was put on the dangerously ill list, with flatus tube and eserine every four hours. On July 31 he was off the "D.I. List"; general condition excellent. On Aug. 2 he could walk round his bed. After an uninterrupted recovery the patient was discharged to sick leave on Aug. 21 in Category "D."

Commentary

The diagnosis of this case in the early stages was difficult. Now that we are "wise after the event," it is fairly obvious that his early signs and symptoms were those of *intermittent partial* obstruction of the small intestine, due to a subacute volvulus. The affected loop was evidently swinging like a ship at anchor, partially folding over and then swinging free again, with temporary remissions of symptoms between July 25, when early laparotomy revealed nothing, and July 28, when a complete torsion of the loop on its mesenteric axis took place, and "stayed put," causing acute obstruction. The customary enormous distension associated with the ordinary volvulus (of the *sigmoid* colon) was absent, as might be expected in this case, where the obstruction was much higher up the tract.

No attempt at fixation to prevent recurrence was made, since all of the expedients recommended are unsatisfactory and ineffectual.

The case is of further interest in that volvulus of the *small* intestine is very uncommon. Tully Vaughan collected 21 cases only; and Rowlands and Turner of Guy's stated in 1937 that "in several cases difficulties were so great and the appearance so puzzling that the operators did not recognize the condition during the operation." J. B. Roberts also refers to two other cases in which the lesion was discovered only at necropsy.

I would like to express my thanks to Brig. R. P. Cormack, O.B.E., D.M.S., East Africa Command, and to Lieut.-Col. R. P. Leake, O/C Station Hospital, Mauritius, for permission to publish this case.

Reviews

BASIC TRAINING IN ANATOMY

Anatomy as a Basis for Medical and Dental Practice. By Donald Mainland, D.Sc., M.B., Ch.B., F.R.S.Ed., F.R.S.C., Dalhousie University. (Pp. 863; 61 figs. 35s.) London: Hamish Hamilton Medical Books.

We are all inclined to hold views on education that reflect the kind of occupation we follow, and on medical education the views are as diverse as the fields of work that fall within the sphere of the medical profession. On one fundamental point there is a dichotomy of views. At the one extreme it is said that the "medical sciences" should provide vocational data, by memorization if necessary, without wasting time on the background or setting of these data; at the other extreme it is claimed that time is well spent on education in basic principles, upon which the vocational data can then be grafted. In the wholesome and refreshing book before us Prof. Mainland's standpoint approaches the latter view, and he has given us a stimulating guide to a course of study in anatomy. Characteristic features of his method are the constant urge to make personal observation on the living subject, and the initiation of the student into the study of the literature.

After a short section with an arrangement that is chiefly historical, Mainland introduces the main part of his work with a section on general anatomy. This is followed by the section on regional anatomy, which occupies three-quarters of the book. A series of appendices has made it possible to omit from the text various details such as ossification dates. Under general anatomy certain systems have been so treated as to stimulate interest in normal and disturbed function; but some systems have unfortunately been omitted. One chapter, on the body as a whole, is a compendium of important topics that often receive insufficient attention in the curriculum, among which mention may be made of growth and age-changes, the effects of environment, and the causes and measurement of individual variation; racial problems are, however, discussed too exclusively with reference to those of the American people. Valuable to the student will be the brief exposition of simple statistical methods. In the section on regional anatomy the author has made a praiseworthy and valiant attempt to give the "lowest common denominator" of the requirements of the various fields of clinical work, in pleasing contrast to the present unfortunate tendency for the curriculum to be the sum of a series of minimum requirements. In this difficult matter of selection it is not possible to please all. Those who expect an encyclopaedia will complain of omissions; some who are engaged in such fields as biochemical medicine and therapeutics may think there is too much. But the author has deliberately set out to cater for the future general practitioner or dentist, and his selection of material has been drawn from a wide field with good judgment. Practical study of the movements of joints has been stressed at the expense of long lists of ligaments. The coronary arteries receive as much space as all the hamstring muscles, while pelvic variations receive four times the space of either.

In his approach to the particular by way of the general, Mainland has avoided an obvious risk that applies to all the medical sciences—that of demanding an effort in the study of principles which may be out of all proportion to the vocational superstructure. The ability of the mediocre student to grasp and apply principles is limited, and the comparative and embryological approaches in anatomy must be as restrained as the elaborate symbolism of chemical structure should be in some other fields. Mainland has found a simple embryological approach useful, for example, in giving us a rationale for the courses of the recurrent laryngeal and phrenic nerves. But he has scarcely explored the possibilities of the comparative approach, while the omission of histology is a drawback that is evidently realized by the author, for he urges on the student the importance of linking up histology with gross anatomy for himself.

Several assumptions are implicit in the style and substance of the book. It is essentially a combination of a practical book with a guidebook to the library; it is not a dissecting manual. Access to a first-class library is indeed essential if full profit is to be derived from the numerous references, which have rendered this book a guide to a far wider field than that covered by the usual overgrown textbook. The extensive bibliography will be valuable to student, graduate, and teacher alike, and it has at the same time relieved the text of much detail that is not wanted by every reader. But the inclusion of some more references to work in languages other than English would have added much to the value of the list, and it would have encouraged wider reading than the English-speaking student (or graduate) is usually willing to undertake. The somewhat synoptic style may be found irritating if one undertakes continuous reading; it is better suited to a notebook—"Cervix is only a button-like projection in vagina" (p. 479). Some of Mainland's words of advice seem more suitable for oral instruction—e.g., on the spelling of the word "plantar" (p. 8). He is, however, probably right when he assumes the student's need for a training in logic, in the use of such words as "explanation" and "normal," and, indeed, in the "Meaning of Meaning"; and he rightly insists on the importance of the accurate use of words and terms for the avoidance of misunderstanding. As the author remarks in his introduction, this work is not an "Anatomy made Easy"; it is a guidebook to hard work and hard thinking. For self-development and the acquisition of essential facts it is highly recommended to the student.

A. B. Appleton.

DIAGNOSIS AND TREATMENT OF MALARIA

Malaria: Its Diagnosis, Treatment and Prophylaxis. By William N. Bispham. (Pp. 197; 5 plates. $3.50, or 19s. 6d.) Baltimore: The Williams and Wilkins Company; London: Baillière, Tindall and Cox.

One result of the war has been the bringing of very large numbers of medical men into positions where, often with little previous experience of the disease, they are called upon to diagnose and treat cases of malaria. To those who find themselves in such a position the recently published volume on the diagnosis, treatment, and prophylaxis of malaria by Col. W. N. Bispham, U.S. Army Medical Corps (ret.), will be found particularly helpful. For while keeping in view the object indicated by the title it gives in an easily readable style just enough about malaria as a whole to make the book generally informative. That this is quite necessary in the achievement of its object will be apparent if one considers that a medical man at the present time cannot competently diagnose or treat malaria without at least some knowledge of the malaria parasites and even about the aetiological cycle and the mosquito that transmits the disease. The merit of the work is that it meets these requirements with just that amount of detail necessary and no more. There is a brief summary of the history of malaria and its distribution. This is followed by a chapter on the aetiology with a brief account of the malaria parasites, and a very brief but adequate chapter on the mosquito and one on epidemiology. Symptomatology and complications are dealt with at greater length, as are diagnosis, treatment, and prevention. There are also short chapters on pathology, malarial immunity, and blackwater fever. Prof. Coggleshall contributes a chapter on the prevention and treatment of malaria in West Africa.

If there be any criticism it is perhaps that some of the sections might with advantage have been fuller. Thus, while emphasis is rightly given to the fact that laboratory diagnosis of malaria is the only positive method, it is doubtful whether the brief directions for technique of blood staining, in which Wright's modification of Romanowski's stain is given with no mention of the almost universal use of Giemsa or Field's stain, are as adequate as they might have been. There are one or two other points that might be criticized, as, for example, the statement on page 43 that three or four feedings are necessary for a mosquito to transmit infection. The book remains a most readable and useful summary for the medical officer in need of information about malaria.

NEUROPSYCHIATRY

Recent Advances in Neurology and Neuropsychiatry. By W. Russell Brain, D.M., F.R.C.P., and E. B. Strauss, D.M. Fifth edition. (Pp. 363; illustrated. 18s.) London: J. and A. Churchill. 1945.

Convinced that, after all, neurology and psychiatry cannot be divorced, especially in view of the new physical therapeutic procedures, the authors have again joined forces to produce this edition. One of the advantages of war is the stimulus given to the study of medicine and surgery, and in no department of the science and art is this more apparent than in neuropsychiatry. Consequently this book has had almost to be rewritten. Attention is paid to such innovations as the modern surgical treatment of head injuries (in a chapter contributed by Northfield); to peripheral nerve lesions; to shock therapy and leucotomy for certain psychotic disorders; to removal of intervertebral disks for sciatica and of the thymus gland for myasthenia gravis; and to the use of penicillin. Diagnostic methods such as electro-encephalography and ventriculography are fully discussed. At the same time the exposition of recent ideas covering practically the whole field of neurology and psychiatry has been brought up to date. It is difficult to see how the neurologist, the psychiatrist, the neuropsychiatrist, or the psychotherapist (whichever title the specialist in this field chooses to adopt) can do without this book, and so rapid is the advance in his chosen subject that he will have to scrap his old editions and buy this new one. Certainly the authors are to be congratulated on their work, but we shall be surprised if they are not called upon to produce a sixth edition very soon.

INTRODUCTION TO COLLOIDS

Colloids: Their Properties and Applications. By A. G. Ward, M.A. Blackie's "Technique" Series. (Pp. 133; illustrated. 5s.) London and Glasgow: Blackie and Son. 1945.

This book on colloids has been prepared with the object of supplying an introduction to the subject more suitable for the beginner than the books which deal with it in more exhaustive and more mathematical detail. It contains illustrative references to a broad variety of subjects, which include rubber, clay, paints, biological phenomena, and detergents. We note a few instances in which there is a lack of a word, a phrase, or a sentence which would have been helpful to the uninstructed, as under the term "solubilization," where it is stated that "many substances which are almost insoluble in water show a considerable solubility in soap and other detergent solutions." But what sort of substances are the many that behave thus? If the text had read, "many substances such as benzene," the reading would have been easier. Yet on the whole the book has been well written, and it contains the right kind of information for the beginner.

The chemistry and physics of colloids have been involved in industrial processes and in the arts since the earliest times; but while this chemistry and this physics have hitherto been empirical, and while the study of colloids has been based largely on established practices, the knowledge of colloids has now reached the stage at which it is applied to guide and govern those practices. Industrialists can therefore no longer omit the study of colloids as an adjunct to their equipment. This book will provide a good foundation for the building of such knowledge.

Notes on Books

The Analysis and Interpretation of Symptoms, edited by Dr. Cyril M. MacBryde, is published by the J. B. Lippincott Company at 25s. The title of this book arouses expectations which are not completely satisfied. It is not so much an analysis of symptoms as a collection of clinical essays by different authors which have already appeared in *Clinics*. Two of these essays have the words "differential diagnosis" in their titles and the subject is approached from this point of view, rather than from that of the clinical scientist or physiologist. The subjects chosen are nervousness and fatigue, fever, headache, thoracic pain, cough, haemoptysis, abdominal pain, haematemesis and melaena, jaundice, joint pains, and obesity. The articles differ in quality; the one on cough and haemoptysis degenerates into a catalogue, while on the other hand Leon Schiff gives an excellent account of haematemesis and melaena, as might be expected from his own research work in this field. In general, however, the text lacks the concentration of a scientific monograph or the unity of a collection of essays by an individual author. The book, which is well produced, has reached a second impression, and one wonders at the market for this type of work in the United States, especially in these days when material and labour for printing books are scarce, and when general practitioners are lucky if they can find time to read the current journals.

We have received from the hon. secretary, Dr. W. H. McMenemey, Royal Infirmary, Worcester, a copy of the first issue of *Proceedings of the Association of Clinical Pathologists,* dated July, 1945, and published at 5s. For some time the Association has felt the need of a journal of its own, and the opening number is a well-produced magazine of 50 pages and a number of plates for photomicrographs. The contents include Dr. A. F. Sladden's presidential address in 1943 on "The Significance of the Laboratory," and five other papers, and a report on the European Association of Clinical Pathologists. The editor is Dr. A. G. Signy, Ashford County Hospital, Ashford, Middlesex.

A *Short Anglo-Polish Medical Dictionary,* by Dr. W. Tomaszewski, has been published by E. and S. Livingstone at 8s. 6d. and 4d. postage. The compilation and printing have had support from the Kosciuszko Foundation of New York. It is appropriate that this booklet should be published by an Edinburgh firm, because the Polish School of Medicine was established in that city during the war through generous action by the University and the civic authorities.

Preparations and Appliances

AN INDWELLING SYRINGE FOR PENICILLIN ADMINISTRATION

Dr. H. F. Barnard, Pathologist, E.M.S. Hospital, Driffield, writes:

The outstanding advantages that penicillin offers are offset by inconveniences that become more apparent as its use spreads to the small hospital and the patient's home, where skilled attention is limited. The three-hourly injection, and the special precautions needed to avoid bacterial or chemical contamination of the solution with consequent loss of potency, call for constantly available skilled help, whilst the continuous drip infusion, though avoiding the distress to the patient of repeated injections, still calls for preparation, care, and watchful attention.

The watch-driven syringe described has been in use at this hospital since November, 1944, and offers a solution to these problems until such time as oral administration or injections of greatly prolonged action are an established alternative.* Last[1] has described an apparatus on this principle using a somewhat larger mechanism, a Record syringe, and a length of rubber tube leading to the patient; whilst Edwards[2] has described a hand-operated Record syringe and tube method.

The apparatus shown in Fig. 1 consists of a plastic base (A), 7 × 2 in., in which is set a pocket watch (B), adapted so that the hour hand drives a toothed rack strip (C) slowly forward, and the dose of penicillin in the syringe (100,000 units in 5 c.cm.) is delivered in 24 hours through a needle bent at a right-angle (D). The apparatus is attached to the thigh by means of adhesive strapping slipped beneath it and over the side-hooks. The all-glass "vim" syringe is then filled, and the right-angled needle, already attached, is guided through the circular hole and inserted into the skin, and the syringe is clipped into position. No further attention is required until 24 hours later, when the syringe is removed, boiled up, refilled, and, after rewinding and adjusting back the watch, is again inserted.

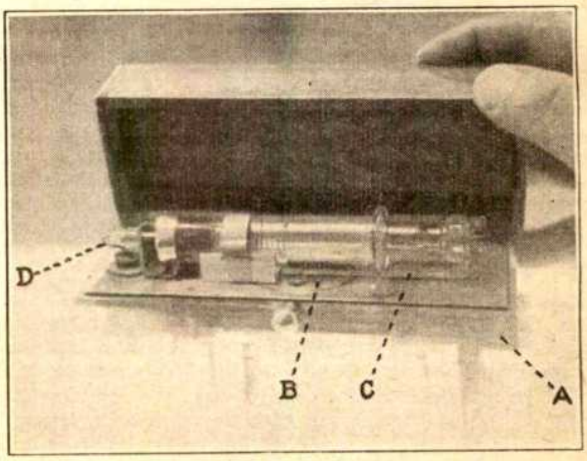

Fig. 1

The basis of the method depends upon the observation that a sterile solution in a good-quality all-glass syringe (such as the "vim") will remain sterile at room temperature at least for many days. At a concentration of 20,000 units per c.cm. penicillin as now available is a gummy product, and tends to jam the syringe unless this is lightly greased with soft paraffin. Paraffin has no harmful effect on penicillin, but the stock bottle of paraffin should in the first instance be autoclaved.

As to stability, Kirby[3] has stated that penicillin as produced at present shows no appreciable loss of potency in solution in four days at 37° C. However, a considerable number of estimations with various makes have shown that, in the conditions of concentration and temperature in the syringe attached to the patient, as described, penicillin deteriorates by the end of 24 hours to approximately 60% of the original; i.e., some 20% of the whole day's dose may be lost. Against this disadvantage one may set the advantages of simplicity, reliability, and constant dosage. One finds that blood taken at the end of a day's run inhibits a test haemolytic streptococcus when diluted 2 to 4 times. Higher levels are obtainable, of course, by a more concentrated solution in the syringe.

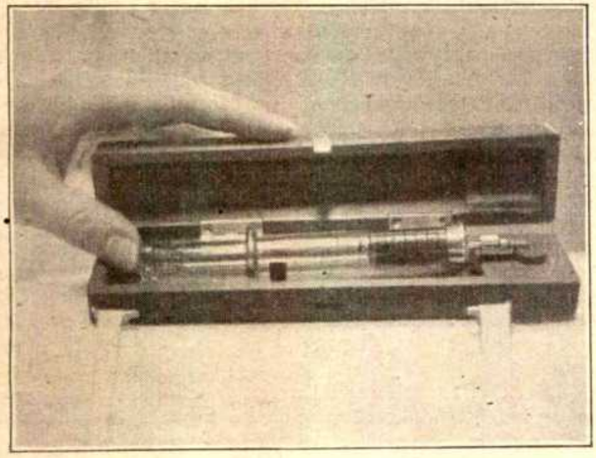

FIG. 2

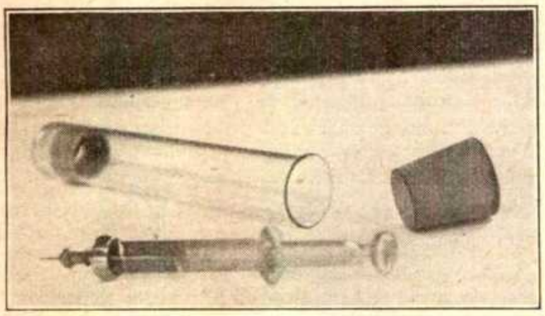

FIG. 3

As a simpler version, the second apparatus is shown in Fig. 2. It has no watch mechanism. The syringe is filled and clipped in as before, and thereafter every three hours the plunger is pushed forward to the next red mark on the syringe, there being eight such red marks. This manœuvre requires no sterility and, as has been proved in general practice, can be carried out in the patient's home by any reasonably intelligent member of the household. No discomfort is experienced by the presence of the apparatus, and the sleeping patient may even be unawakened by the giving of a dose.

Fig. 3 shows how the method can be applied to the keeping and giving of drops of penicillin for an eye or ear case (and also to many other procedures, such as blood grouping). The syringe with the needle cut short keeps the solution sterile through many manipulations and is stored in a tube with cork ring as shown, to keep the needle from touching the tube.

The syringes, needles, and box for the hand-operated method are obtainable from Messrs. Chas. F. Thackray, Ltd., 10, Park Street, Leeds, 1. It is hoped that the watch-driven apparatus will become available before long, shortage of materials having held up production for some months.

I wish to thank Dr. Panton, Director of the E.M.S. Pathological Service, for permission to publish this, and Flt. Sergt. Foulkes for his skilful work on the watch-driven model.

MEDICAL DEFENCE UNION

ANNUAL MEETING

The Medical Defence Union, which is entering upon its sixtieth year, held its annual meeting on Sept. 16, when Mr. St. J. D. Buxton was unanimously elected president, Dr. Henry Robinson treasurer, and Dr. G. Roche Lynch chairman of the council committee. The retiring officers—namely, Dr. James Fenton, who relinquished the chair at that meeting, and Mr. E. D. D. Davis, the late treasurer—were congratulated on the manner in which they had discharged the functions of their offices and were thanked for their services.

Dr. **JAMES FENTON**, in a valedictory address, referred to the work of the council and its committees during the war. In the early days the staff was transferred to the suburbs, but in view of the inconvenience caused to members who came personally to seek advice, a return to Bedford Square took place in 1942. The Union had come through the war ordeal without scars and with increased strength, for since 1938 the membership had gone up by just upon 8,000, and stood to-day at 28,483.

In a reference to the very special problems facing demobilized medical practitioners, Dr. Fenton said that it was desirable to make it widely known that members of the Union returning to civil life would have everything possible done, within the scope of the Union's activities, to ease their burden if they needed such assistance. He urged again that members should provide headquarters with early information when they were threatened with litigation arising out of their medical practice. Not infrequently such cases were prejudiced by delay in seeking the Union's advice or by the taking of preliminary action without such consultation.

Joint Action

Good progress had been made, Dr Fenton continued, in discussions with the London and Counties Medical Protection Society and the Scottish Defence Union with a view to the establishment of a joint co-ordinating committee. The main object of this committee would be to define the broad policy to be pursued in common by the three societies, and it was also anticipated that matters arising from cases affecting members of any two of the societies, or all three of them, could be discussed and suitably determined. Each society would retain its separate individuality and freedom of action, but the societies would act jointly where a community of purpose would be served by so doing.

Some time ago the M.D.U. started consultations with the Society of Anaesthetists and the manufacturers of anaesthetic gases with the object of preventing the repetition of the few, but unfortunate, accidents which have arisen owing to anaesthetists giving gases from wrong cylinders. The problem had proved a difficult one owing to the need for experiment and the preparation of new forms of couplings. Even the colouring of the cylinders, which was one of the questions coming forward, was not a simple matter, because cylinders produced and used in other countries were affected. A short-term policy had been adopted for the transitional period, and those concerned were now engaged on a long-term policy dealing with new devices in order to make the apparatus foolproof.

He added that an increased number of cases in which advice was sought were being brought forward by doctors engaged in whole-time work for local authorities, and there had also been a number of difficulties to solve on behalf of medical officers working part-time for local authorities in clinics and dispensaries. The address concluded with a tribute to the legal adviser of the Union, Mr. Oswald Hempson, and to the secretary, Dr. Robert Forbes, and his staff.

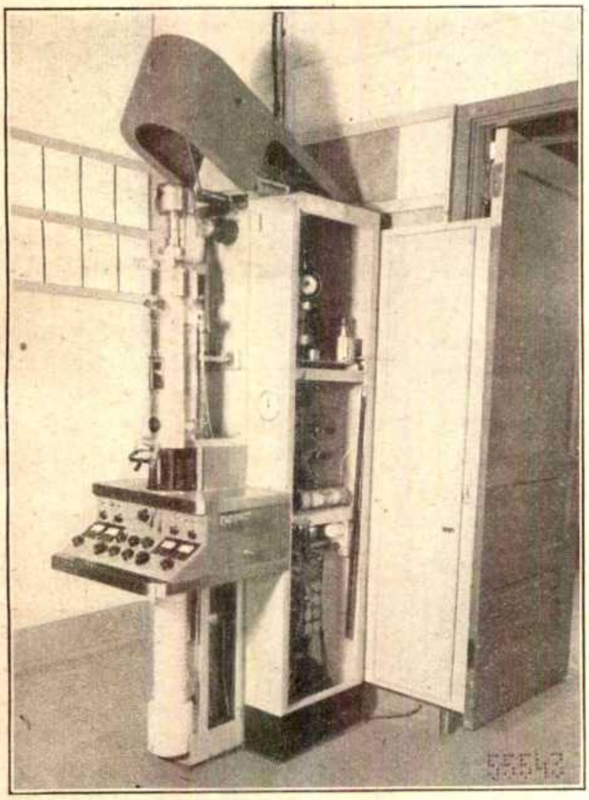
The Minister of Supply has made an Order which revokes and remakes in consolidated form the Control of Molasses and Industrial Alcohol (Nos. 11 to 17) Orders, 1941–2. Methanol, formaldehyde, metaformaldehyde, and hexamine are released from control, and licences will no longer be necessary for the acquisition, disposal, treatment, use, or consumption of these commodities. The maximum quantity of industrial alcohol (other than mineralized methylated spirits) which can be acquired, disposed of, treated, used, or consumed without a licence is increased from one gallon a month to sixty gallons in six calendar months.

THE ELECTRON MICROSCOPE

BY

JOHN H. JUPE

The electron microscope has been developed to overcome the limitations of the ordinary light microscope—limitations which have been hampering certain branches of scientific research. Little could be done to overcome these, however, until a fundamental discovery showed that electrons in motion could be deflected by an electrostatic or magnetic field. This can best be explained as follows. First, consider the electrons as charges of negative electricity. As such they will be attracted or repelled by electrostatic fields. But also, electrons in motion constitute an electric current, and as such will be deflected by magnetic fields. By producing either of these fields with the requisite strength and formation, groups of electrons travelling along a path in a vacuum can be concentrated or caused to diverge. Hence arises the term "electron lenses," which act on the electron stream in much the same way as glass lenses act on light.



R.C.A. universal electron microscope (covers removed). The cabinet housing the 50 kilovolt power supply is at the rear.

General Description

In the electron microscope there is an electron source—usually a heated cathode—corresponding to the light source of the ordinary microscope; there are also analogous electronic condensing and objective lenses. The electron stream is accelerated to very high speeds by the use of high voltages, and it takes on the characteristics of any thin object placed in its path. It is then allowed to fall on to a fluorescent screen, where a shadow image of the object appears. The whole process is very similar to screen radiography, except that cathode rays are used instead of *x* rays. In the same way, the results are only shadows of varying density and are not the images obtained by the usual reflection of light from objects—i.e., normal human vision, or an ordinary photograph.

The general appearance of one of the latest forms of the electron microscope is shown in the Fig. At the top of the stainless-steel column are housed the hot cathode for producing the electron stream and an electron "gun" for concentrating it. At the bottom of the column, just above the control desk, is the triple-sided viewing chamber. Below the panel is the oil diffusion pump for creating the necessary high vacuum in the microscope column; and in the cabinet at the rear is the 50,000 volt power supply unit and electrical control circuits.

The specimens are inserted through the round aperture immediately above the "first" image-viewing window. In the middle of the column, and to save the necessity for evacuating the whole of the microscope each time it is desired to change a specimen, there is a small chamber fitted with air locks. A similar device is used when the fluorescent screen for viewing the final image is replaced by a photographic plate. The instrument illustrated is made by the Radio Corporation of America and is considered to be the most powerful type of microscope in the world. Its direct magnification can be varied in 40 steps from 100 to 20,000 times; and with it the naked eye can see details as small as a quarter of a millionth of an inch. By taking photographs with this apparatus, normal photographic technique will permit the final magnification of the object to be more than 100,000 diameters.

Limitations and Achievements

It may be asked whether the electron microscope has parallel limitations to the light microscope. The answer is that it has, and for the same reasons—i.e., it is dependent on the resolving powers of the electron lenses, the human eye, and the photographic plate, and also on the wave-length of the electron stream. In the case of the electron microscope, however, the limitations are theoretically about 100,000 times smaller—i.e., it should be possible to produce magnifications of 200,000,000 diameters, since the best optical microscopes, using glass lenses and visible light, have a maximum limit of about 2,000 diameters. There are reasons for believing that the maximum resolving power may never be achieved, but this is not serious from the point of view of the practical microscopist engaged in bacteriology, pathology, physics, metallurgy, etc., since magnifications 10 to 1,000 times greater than those of the ordinary microscope are of immense value.

Already a number of viruses have been observed for the first time, and the specific action of substances on bacteria have been investigated more closely.

Mounting of Specimens

Mounting specimens for the electron microscope is more difficult than for the more usual type of instrument, because the cathode-ray stream is stopped by anything thicker than about a millionth of an inch. The usual support is a film of nitrocellulose, not exceeding this thickness and itself supported by a metal gauze disk with about 200 meshes to the inch. To prepare such a thin film, a solution of nitrocellulose in a suitable solvent is placed on water and allowed to spread until a satisfactory thickness is attained. The metal disk is then placed on top of it, and a film of the desired thickness will harden between the meshes. The specimen is suspended in a volatile solvent, and a drop is placed on the film and allowed to evaporate.

Future Possibilities

In general, the technique of using the microscope is not very difficult and can be mastered by medical research workers in quite a short time; the apparatus is made perfectly safe from the point of view of high voltages and the user. What revelations lie ahead in the development and use of this instrument cannot be known. It is quite probable that it will help to settle the controversial question as to the exact dividing-line between living and dead matter.

My thanks are due to the Radio Corporation of America for providing the illustration.

The Medical Committee of the Scientific Film Association (c/o Royal Photographic Society, 16, Princes Gate, S.W.7) has issued a third handlist of recent films of medical interest. The three new films in the "Technique of Anaesthesia" series and "Movement of the Tongue in Speech" and "Penicillin" have all been completed very recently. "Effect of Thymectomy" is an amateur record for which the S.F.A. has obtained funds for copying and distributing; it hopes to make many more such films available as resources permit. "The New Lot" and "Evacuation of Casualties by Air" are both Services films which may now be shown to non-Service audiences.

NUTRITIONAL MACROCYTIC ANAEMIA

The sternal puncture needle, by enabling us to study the bone-marrow almost as easily as we can the blood, has cleared up some of the obscurity about pernicious anaemia and its congeners. We know now that the pathognomonic feature of this large group of deficiency diseases of the blood-forming organs is the proliferation of megaloblasts in the bone-marrow and the restoration of the normal type of erythropoiesis by liver.[1] This may take place in circumstances in which the peripheral blood is not frankly megalocytic, as in some cases of pernicious anaemia of pregnancy[2] and tropical macrocytic anaemia.[3] On the other hand, the blood picture in aplastic and haemolytic anaemias may sometimes be megalocytic, but the bone-marrow is not megaloblastic and treatment by the pernicious anaemia (P.A.) factor is ineffective. In accordance with Castle's hypothesis of extrinsic and intrinsic factors the megalocytic deficiency anaemias can be further subdivided into those which are due to a defect in the diet, the nutritional macrocytic anaemias, and those which are due to a disturbance in the digestion, of which Addisonian pernicious anaemia and sprue are the chief examples. This distinction must not be pressed too far, for dietary deficiencies have a way of impairing digestion, as has been only too sadly verified in recent experiences of starvation in Europe. The laboratory data in nutritional macrocytic anaemia differ in three ways from those commonly found in pernicious anaemia: (1) hydrochloric acid is usually present in the gastric juice; (2) the serum bilirubin is within normal limits; and (3) the serum iron is usually not elevated.[4]

Nutritional macrocytic anaemia is so prevalent that it might have been expected that the enormous number of cases would have enabled us to work out the chemistry of the extrinsic factor and the P.A. principle. Unfortunately this has not yet happened. It is difficult to carry out controlled therapeutic trials in tropical and subtropical countries owing to the poverty of hospital and laboratory resources and the temperament of the patients. Moreover, like most dietary defects, nutritional macrocytic anaemia is often complicated by multiple deficiencies, and by infections and parasitic infestations. A deficiency of iron so frequently occurs at the same time that the useful name "dimorphic anaemia" has been introduced.[5] Haemolysis may be provoked by concomitant malaria, and pregnancy is a common cause for the final breakdown. Nutritional macrocytic anaemia is also more often resistant to treatment than Addisonian pernicious anaemia, particularly to treatment by highly purified extracts of liver. This has led to the suggestion that whole liver and proteolysed extracts of liver contain active principles which are lost during purification.[6] It is possible, however, that the difference is merely one of dosage; with purified intramuscular extracts it is unusual to give more than 0.2 g. of liver solids a day, while with proteolysed extract of liver the dosage is 50 g. a day. Moreover, resistance is sometimes due to recognizable inhibitory influences such as pregnancy or infection, and it is not in itself a strong argument for a chemical difference in the nature of the haematinic principles which are lacking in pernicious anaemia and nutritional macrocytic anaemia. Nevertheless, all these complications make research on nutritional macrocytic anaemia a difficult and tedious business.

Much confusion has existed about the pathogenesis of the macrocytic anaemia of pellagra and other forms of vitamin-B deficiency. The incidence of this anaemia varies widely in different parts of the world and in the different types of avitaminosis B. In Egypt, Salah[7] found no macrocytic anaemia among 118 pellagrins. In endemic pellagrous areas of the United States, Huck[8] and Turner[9] found anaemia uncommon, and, when present, usually hypochromic and microcytic in character. Among the so-called alcoholic pellagrins, Spies and Chinn[10] found macrocytic anaemia to be relatively common. The anaemia has been variously ascribed to lack of a specific B factor, deficiency of Castle's extrinsic factor, and loss of the intrinsic factor. Since the B complex and the extrinsic factor are often closely associated in nature, and since pellagrous diets are frequently deficient in both, it has hitherto been difficult to determine which, if either, plays the decisive part in the production of the anaemia. The frequency of absolute achlorhydria in pellagra has lent support to the view that the anaemia results from absence of the intrinsic factor. Nevertheless, little information has been available about the intrinsic factor of the gastric juice in this disease; it has been demonstrated in a few instances, but only in patients in whom there has been no significant anaemia. Furthermore, the incidence of achlorhydria appears to vary; Sodeman[11] found it in 55 out of 77 pellagrins, whereas Moore, Vilter, Minnich, and Spies[4] demonstrated free HCl in the gastric juice at one or another time in as many as 21 out of 25 pellagrous patients.

The question of the pathogenesis of this anaemia has now been decisively answered by Moore and his co-workers. They have studied 25 patients with pellagra in whom glossitis, dermatitis, and peripheral neuritis were associated with a severe macrocytic anaemia. The diets of these patients had for many years been grossly deficient in all the members of the B complex and in animal protein. The anaemia was cytologically indistinguishable from Addisonian anaemia, but in 21 of the 25 patients free hydrochloric acid was found in the gastric juice. The American workers were able to demonstrate the presence of intrinsic factor in the gastric juice of two of their cases by the production of a reticulocyte response when patients with Addisonian anaemia were treated with a mixture of pellagrous gastric juice and extract of raw beef muscle. Having shown in this way that the anaemia was not due to an intrinsic defect, they then proceeded to study the reticulocyte response in the pellagrins while they were kept on a standard diet deficient in both the B complex and Castle's extrinsic factor, in order to determine the specific nutritional deficiency responsible for the anaemia. After a control period on the diet, massive oral and parenteral therapy with all the known B vitamins was tried, and though the clinical manifestations of avitaminosis were relieved there was no change in the reticulocyte count. Nicotinic acid, thiamine, riboflavin, calcium pantothenate, pyridoxine, inositol, para-aminobenzoic acid, and choline had no therapeutic value in correcting the anaemia, even though they were given in combination both orally and parenterally. Administration of highly purified liver extracts, however, caused prompt haematological and clinical improvement. When extract of raw beef muscle was ingested daily a suboptimal reticulocyte response occurred which was followed by a rise in the red cell count and clinical remission. In one of these patients there was a further small rise in the reticulocytes when a mixture of normal human gastric juice and beef extract was ingested, and again an increase in reticulocytes followed by acceleration of the rise in red cell count when purified liver extract was given parenterally. All the patients, in whom the reticulocyte response was suboptimal when beef extract was ingested, exhibited a second reticulocyte response after intramuscular injection of purified liver extract.

Moore and his colleagues conclude that none of the B vitamins they used can act as the extrinsic factor, and that the macrocytic anaemia of pellagra depends on a prolonged deficiency of Castle's extrinsic factor in the diet. This is associated in many instances with poor absorption from the gastro-intestinal tract and in some cases with inadequate production of intrinsic factor by the gastric mucosa. Most of the patients were observed for two or three years, and, as would be expected, the few who corrected their faulty dietary habits remained well without further liver therapy. These findings provide an explanation of the variable incidence of macrocytic anaemia in pellagra. Though the sources of the B complex and the extrinsic factor are frequently identical, deficient dietaries may be lacking in one or other as well as in both. A high incidence of macrocytic anaemia unaccompanied by avitaminosis has recently been reported in this *Journal* among Indian troops on an exclusively vegetarian diet,[12] whereas it is probable that the diets of pellagrins in Egypt and the endemic areas of the United States, where the incidence of macrocytic anaemia is low, contain adequate amounts of the extrinsic factor though deficient in the B complex.

Finally, we must emphasize that this excellent American study is a challenge to British haematology. The British Empire is the world's largest reservoir of nutritional macrocytic anaemia, and it is painful that English haematologists should be expending their skill on the minutiae of their craft at home when such important work awaits them in the field. A cheap remedy for nutritional macrocytic anaemia would greatly enhance the vigour of tropical and subtropical populations. To discover it there are some obvious immediate steps. The first is the creation of a research centre or centres in a situation where large numbers of patients with nutritional macrocytic anaemia can be attracted and treated. The second is the fractionation of beef muscle by the same kind of technique as the Harvard group[13] has developed for plasma and the study of the separate fractions to locate and isolate the extrinsic factor. The third is the purification and characterization of the liver principle. These problems have hung in the wind for the last ten years, largely as a result of the war and the impossibility of sending research teams over-seas, but the war itself has shown how important the problem of nutritional macrocytic anaemia is, and how urgent, therefore, it is to create an organization to deal with it.

ARTIFICIAL LIMBS

The recent White Paper[14] setting out the report of the Departmental Committee appointed by the former Minister of Pensions, Sir Walter Womersley, gives a good survey of the fitting and supply of artificial limbs. It is a carefully compiled document presenting information of value to all concerned with the welfare of those who have undergone amputation. Previous reports have necessarily dealt with Service cases only, but now that the Ministry's limb-fitting organization is employed by other Government Departments, and by other bodies who provide artificial limbs, it affords a useful review with some welcome recommendations.

At the end of the 1914–18 war artificial limbs were made of varying designs by many firms. With the large number of Service cases there was no one firm capable of supplying all the prostheses required. As the various types were tried it became manifest which designs were better suited for the use and comfort of the patient. Ultimately it could be decided which were the essential features to be incorporated in a uniformly constructed and comfortable prosthesis for each site of amputation. It appears from the evidence of witnesses representing large numbers of pensioners and from reports received (as set out in Appendix 1) that the present artificial leg is of sound construction and design, giving general satisfaction. Reviewing the recommendations set out there still appears room for improvement in some types of leg, and a like conclusion seems to have been reached regarding the artificial arm. One might well think that it is against progress to eliminate competition by placing the contract for the manufacture and supply of limbs with one firm. The White Paper declares, however, that when new designs of legs and arms and of appliances are submitted and proved to be of value they will be incorporated to improve the prostheses. A standing advisory committee has been specially appointed to investigate all proposals submitted and to have any new development critically examined and tested. This procedure should ensure further progress and enable all types of patients to have their requirements specifically catered for.

[14] *Artificial Limbs.* Ministry of Pensions, 1945. H.M. Stationery Office. Price 4d.

Whereas before the present war the Ministry of Pensions mainly supplied only ex-Service men with prostheses, there are now many civilians, including women and children, who have been injured by enemy action to be considered. The Ministry of Education also uses the Ministry of Pensions' organization to provide school-children with such prostheses as are required for congenital and other cases. This new branch of the work certainly calls for more individual care from the surgeon and the fitter, as indicated in the report. It is to be hoped that some of the committee's recommendations will soon be put into effect. Individual attention by one surgeon and the same fitter is a major factor in the rehabilitation of the person who has lost a limb. The surgeon responsible for examining a patient, advising the correct treatment of the stump before limb-fitting, and ultimately specifying the proper type of limb for the site of amputation needs to be a man who can inspire the patient's confidence. He can, with the co-operation of the fitter and repeated examination of the patient, ensure a successful fitting of the prosthesis. Now that limb-fitting is regarded as a specialized practice the recommendations in paras. 21 and 22 are of primary importance: there is need for skilled surgeons with both medical and technical knowledge who will work closely with the limb-fitter. The Ministry's policy in employing surgeons for this work will no doubt be copied in other countries where so far it has been handled only by the limb-maker.

Careful records of all relevant data concerning patients and their full subsequent limb-fitting history should be published for the guidance of those dealing with the limbless in all countries. This would very often be of inestimable value to surgeons before the actual amputation is performed. Are the committee's recommendations that a patient might have the limb on trial in the rough stage being seriously considered and carried out? There appears to be a controversy on the question whether the patient should have a wood or a metal limb for a below-knee amputation site: the advantages and disadvantages of each might well be published for guidance. Artificial arms need a specially detailed study with regard both to the arm and to all appliances used. The replacement of the natural hand by anything approaching it presents a very difficult problem. It is to be hoped, however, that no effort will be spared to obtain useful industrial employment for the man who has lost an arm—something which needs more skill than the job of messenger or lift-attendant.

The methods used for re-educating and training those who have lost a limb are clearly set out and fully confirm what has already been published in many journals upon rehabilitation generally. As a result of the committee's recommendations, together with the suggested technical improvements summarized in Appendix 4, and any other suggestions which may be submitted at various times, we may hope that the experience of the Ministry of Pensions will further benefit all people throughout the world who have undergone amputation. The report is a very fair and useful criticism of the work of the limb-fitting organization of the Ministry, whose staff have shown great forethought in establishing a system capable of being extended to cover the requirements of Service and civilian cases from the outbreak of the war, as well as supplying artificial limbs to patients from Allied countries, and also maintaining the system for patients injured in the last war for whom it was originally devised.

PERNICIOUS ANAEMIA AND CARCINOMA OF THE STOMACH

Interest in the coexistence of pernicious anaemia and carcinoma of the stomach dates back to 1876, when Quincke is said to have called attention to such a case. It has grown as the diagnosis of pernicious anaemia has become more accurate and as patients with pernicious anaemia have been kept alive by treatment with liver. A gastric tumour has been discovered as late as 17 years after the diagnosis of pernicious anaemia, and it seems clear from the Mayo Clinic[1] statistics that the concurrence of both benign and malignant tumours of the stomach with pernicious anaemia has increased since the anaemia has been brought under control. There is nothing to suggest that the liver principle is carcinogenic; on the contrary, gastroscopic and microscopical examinations of the gastric mucosa suggest that liver extract tends to arrest inflammatory and degenerative changes in the stomach as in the tongue. The extensive literature has been reviewed recently by Kaplan and Rigler,[2] who have also analysed 43,021 consecutive post-mortem reports in the Department of Pathology of the University of Minnesota from this point of view. Their task has been made harder by the fact that, although pernicious anaemia is more easily diagnosed in life than after death, there has been a tendency to regard any severe anaemia occurring in association with carcinoma of the stomach as due to the carcinoma and not to study it further. It seems doubtful whether a carcinoma of the stomach could produce pernicious anaemia by its action on the gastric mucosa, for complete removal of the stomach in animals and man is rarely followed by the development of pernicious anaemia, and it is more probable that when the two diseases occur together it is because both are the result of similar hereditary or acquired characteristics of the gastric mucosa. In their own series Kaplan and Rigler found that there were 36 cases of known association of pernicious anaemia and carcinoma of the stomach among 293 cases of pernicious anaemia. This represents an incidence of gastric carcinoma in 12.3% of all cases of pernicious anaemia coming to necropsy. The incidence of gastric carcinoma among all other necropsied individuals of comparable age was slightly less than 4%—less than one-third of that found in individuals with pernicious anaemia. Statistically there was decisive evidence for an aetiological relation between carcinoma of the stomach and pernicious anaemia.

The conclusion that Kaplan and Rigler drew from this study was that patients with pernicious anaemia should be submitted to clinical and *x*-ray examination at regular intervals to secure early detection of new growths of the stomach. This procedure would provide an opportunity for the study of the earliest signs and symptoms of carcinoma of the stomach and for the analysis of the hereditary and constitutional factors at work. Moreover, it would be more profitable and practicable a method of early diagnosis of carcinoma of the stomach than the routine *x*-ray examination of all individuals over 50, as less than 1 in 1,000 people in these groups will be found to have carcinoma of the stomach at any one survey. Admittedly not more than 5% of all patients with carcinoma of the stomach will have suffered from pernicious anaemia, but study of pernicious anaemia may enable us one day to pick out the individuals with precancerous lesions of the stomach. Rigler, Kaplan, and Fink[3] have therefore kept 211 patients with pernicious anaemia under observation, examining the stomach usually twice a year but occasionally at longer intervals. The maximum number of *x*-ray examinations per patient so far is eight. Already carcinoma of the stomach has been found in 8% of the patients and benign polyps in 7%. These figures seem high, but the presumption is that they will finally rise higher, to the level of the 12% found in the post-mortem room. The detection of benign polyps is of cardinal importance, as these tumours so often become malignant. The characteristic malignant growth in the stomach in pernicious anaemia is a bulky polypoid tumour, and the sequence appears to be atrophy of the gastric mucosa, benign polyp, and finally adenocarcinoma. The problem of dealing with these benign polyps in the individual patient is difficult. If the lesion is not more than 4 mm. in diameter Rigler and his colleagues prefer to watch and await developments. When the tumour is larger, resection is advised, even though it seems benign. These American studies are very convincing, and it is desirable that regular clinical and *x*-ray examinations of the stomach in pernicious anaemia should become the customary practice.

CAFFEINE AND PEPTIC ULCER

Already in 1904 Allard[4] observed the production of acute gastric erosion and haemorrhage, in man and dog, after the ingestion of synthetic theophylline, and numerous later workers have confirmed that drugs of the caffeine series, administered orally or by injection, may induce acute gastric erosion within a few hours. Roth and Ivy,[5] who have shown previously that the development of the caffeine-induced ulcer is associated with increased secretion of acid and pepsin, and that it can be accelerated by alternate administration of caffeine and histamine, have now[6] studied sections of the gastric mucosa of the cat excised serially by a special technique at intervals of 15 minutes after the slow intravenous injection of 250 mg. caffeine sodium benzoate. They describe a regular sequence of changes in the mucosa: vasodilatation and engorgement followed by vascular stasis, local anoxia, increased capillary permeability, transudation, extravasation of blood elements, and proceeding finally to decreased cell nutrition. Roth and Ivy are accordingly of the opinion that the acute caffeine-induced ulcers arise by the digestive effect exercised by pepsin and hydrochloric acid, formed in excess, upon a gastric mucosa specifically devitalized by circulating caffeine. They add that the pharmacodynamic action of caffeine upon the stomach may or may not be partly or wholly dependent upon its excitatory action on the central nervous system.

Merendino and his fellow-workers[7] have examined the effect of daily intramuscular injection of caffeine alkaloid in a beeswax medium in guinea-pigs and cats. Four out of 10 guinea-pigs and 11 out of 26 cats developed typical punched-out ulcers. In dogs with prepared gastric pouches it was shown that the subcutaneous injection of 1,200 mg. of aqueous caffeine alkaloid, or the daily intramuscular injection of 2,500 mg. of caffeine alkaloid in beeswax, increased the volume and acidity of gastric secretion. This effect persisted even after division of the vagus, and is presumed to be due to the direct action of caffeine upon the gastric mucosa. This experimental work is not without direct and immediate application to man. Merendino has verified that two cupfuls of coffee taken by mouth or by stomach tube increase the volume and acidity of gastric secretion, and that the increase is most dramatic if the coffee is drunk cold and black. Judd[8] in 1942 reported the perforation of a peptic ulcer in a young man, with no previous experience of dyspepsia, after the ingestion of 150 bottles of coca-cola during a five-day heat-wave. Another patient, whose duodenal ulcer proved highly resistant to treatment, proved to be a coca-cola addict. The relation of peptic ulcer to caffeine in these two clinical examples may not be entirely causal, but the experimental work brought together in the papers cited is at least an adequate justification for eliminating caffeine-containing beverages from the diet of ulcer patients.

A NEW REACTION TO EMOTION

Our knowledge of the physiological changes that occur in the body during emotion has hitherto been confined to the increased activity of the sympathetic system, which reinforces its own effects by liberating adrenaline from the suprarenal gland. During fear or anger there is a rise of blood pressure, with increased rate and force of heart-beat, inhibition of the intestines, and pallor of the skin—all changes recognized to help the body to defend itself, and produced by the agency of the sympathetic system. Recent work by E. B. Verney and his colleagues has now brought to light another mechanism which is set in action by emotion and which again involves the discharge of a hormone into the blood stream. Working in the Pharmacological Laboratory in Cambridge on the release from the pituitary posterior lobe of the hormone which controls the loss of water through the kidney, Theobald and Verney[9] observed that "stimuli ranging in severity from shaving the skin to lumbar puncture inhibit water diuresis for varying periods of time." Rydin and Verney[10] later found that diuresis caused in a dog by giving water was also inhibited by a powerful auditory stimulus such as the sounding of a motor-car horn, or by an electrical stimulus applied to the skin.

It seemed very likely that these inhibitory effects were due to the sympathetic. Verney has taken the greatest care to demonstrate that the sympathetic plays no part in this inhibition. Of the series of brilliant researches which form an unbreakable chain of evidence it is possible to mention only one or two here. To demonstrate that the change in the kidney which inhibited diuresis was produced by a hormone carried in the blood, Theobald and Verney[9] prepared a dog in which they achieved the apparently impossible aim of separating one kidney from all tissue connexion with the rest of the body, and accomplished this without interruption of the blood flow through the kidney for more than "a fraction of a second." They were able to show that the kidney in these circumstances functioned normally; diuresis followed when water was given to the dog by mouth. This diuresis was inhibited by sensory stimulation of the skin of the dog's back. The inhibition must therefore have been hormonal; it was not due to adrenaline, because adrenaline did not exert an antidiuretic effect of the kind which was observed. The final link in the chain of evidence was obtained by O'Connor and Verney,[11] who demonstrated that the antidiuretic effect of sensory stimulation was reduced to negligible proportions by removal of the greater part of the posterior lobe of the pituitary gland. Verney has thus established the existence of a new reflex pathway which is followed by powerful sensory stimuli. Probably the stimulation reaches the supra-optic nucleus in the hypothalamus, and the impulses which travel to the posterior lobe are relayed from it. The discovery prompts further questions. What other impulses are relayed from this region of the brain in response to such stimuli? Is it only the antidiuretic hormone which is released from the posterior lobe?

We would like to conclude this outline by referring to the exceptional surgical skill which has characterized this work. A second example in addition to the one already given is that Lockett, O'Connor, and Verney[12] prepared dogs with an exteriorized renal artery. One kidney is brought to lie directly under the skin and the renal artery to this kidney is surrounded by a cuff of skin. Thus it is possible to pass a finger along the dog's back and under the renal artery. The effect on water diuresis of occlusion of the renal artery for any length of time can then be observed. Dogs thus prepared remain in good health indefinitely.

SPROUTING LEGUMES

The soaked pea, the subject of seed germination, has been studied from many aspects, and new facts about this phenomenon are coming to light. Among them the rapid development of vitamins by sprouting legumes must be considered not only interesting but also of practical importance. As early as 1912 Fürst had suggested that in military operations the use of germinated seeds might prevent scurvy. Chick and Delf[13] in 1919 showed that, while dried peas and lentils were useless as a source of vitamin C, on sprouting they became valuable antiscorbutics. Other investigators confirmed these findings, and it was also observed that there was a significant increase in the amount of the B vitamins: in particular, riboflavin and nicotinic acid have been found to increase on germination of legumes, although the amount of B_1 appears to remain unchanged. The importance of applying this knowledge in time of scarcity is obvious, especially when it is realized that, except for their vitamin content, dried legumes have high nutritional value and are also compact and light for transport. In Australia their value became evident in the early stages of the Pacific war, and the Australian Army, working through the Council for Scientific and Industrial Research and the facilities of Adelaide University,[14] issued routine instructions for the proper sprouting of the blue boiling pea (*Pisum sativum*). Although this pea has been found to be one of the most satisfactory legumes for the required purpose, green gram (*Phaseolus mungo*) and soya bean are also frequently quoted. Haricot and navy beans (*Phaseolus vulgaris*) cannot suitably be used, as the rate of germination is so slow that they tend to putrefy before sprouting.[15]

The method usually recommended is a preliminary soaking in water for about 8 to 18 hours in a large burlap bag, or, on a household scale, in a colander. The temperature at this stage is important, as if too high it will induce putrefaction, and if too low it will inhibit germination. About 25° C. is considered a satisfactory temperature. At the end of the soaking period the legumes are drained and germination is allowed to proceed for about three days after commencement of the preliminary soaking or until the shoots are about 2 in. long. Occasional immersion in water, followed by draining, may be necessary over this period. Cooking is best carried out by the conservative method,[16] using a small quantity of water in a covered saucepan. A recent correspondent to this *Journal*[17] pointed out that bean sprouts have been eaten by the Chinese from time immemorial. A survey[18] of the vitamin content of germinated legumes carried out by French and his colleagues at Washington, D.C., gives the following figures in mg. per 100 g. of sprouted pea: ascorbic acid, 25.0; riboflavin, 0.35; nicotinic acid, 1.40; thiamine, 0.24. According to the figures of Lugg and Weller[19] the loss of vitamins during cooking would appear to be about a third of the initial values. These results suggest that the retention of the vitamins may be of the same order as found when the more generally accepted vegetables are cooked. Any food which is recommended for its nutritional value must also conform to accepted standards of palatability. The opinion of French and his colleagues that the final product is highly acceptable as a palatable food as well as an accessory source of vitamins is therefore to be regarded as a further important feature of the phenomenon of the sprouting legume.

UNDULANT FEVER IN THE TRANSVAAL

The annual report of the medical officer of health for Pretoria for 1943–4 is signed by Dr. T. Lötter, who has been acting M.O.H. during Dr. H. Nelson's absence on active service. Besides much information, largely statistical, it includes a note on the menace of undulant fever by Dr. Adrianus Pijper, pathologist to the Pretoria Municipality. Of the three microbes which cause different diseases of the same type *Br. melitensis* and *Br. abortus* are of importance to South Africa. Dr. Pijper's contribution is confined to what he has come across in the way of blood tests done for the diagnosis of undulant fever during the period 1939 to the end of the first quarter of 1944. In a little over five years he found 102 persons who gave a positive test, though only a fraction of these cases were officially notified. Making every allowance for uncertain factors, he concludes that there must be much more of this kind of infectious disease about than is usually thought, and that the incidence in and around Pretoria is certainly not decreasing but rather the reverse. He has good reason to believe that a number of cases completely escape detection and that Charles Nicolle's warning, that undulant fever was a disease of the future and would become more and more prevalent, seems justified by the course that events are taking. The subject is being actively pursued by the veterinary workers at Onderstepoort in so far as animals are concerned, but as usual the medical side is lagging behind. Dr. Pijper points out that it is not laboratory research on the human side that is needed in the first instance: general practitioner and physician specialist should pay more attention to the subject. At the moment both the laboratory worker and the public health official are very much in the dark as to where they should begin. It is for the G.P. and the physician to give them a lead.

Dr. A. J. Orenstein has been promoted major-general, the first medical man in South Africa ever to reach that rank. He has now retired from the South African Army and gone back to his post as chief medical officer of the Rand Gold Mines. Dr. Orenstein has received the C.B. and the C.B.E. during this war, and in the last war the C.M.G.

TRAINING NURSES FOR THE COLONIES

A RUSHCLIFFE COMMITTEE REPORT

A committee under the chairmanship of Lord Rushcliffe was set up by the Colonial Secretary in 1943 to examine the question of the training of nurses for the Colonies and has lately reported.[1] Among its 17 members the committee included 6 doctors—namely, Dr. Mary G. Blacklock, Dr. W. H. Kauntze, Dr. H. M. C. Macaulay, Dr. H. A. Moody, Mr. Arnold Walker, and Dr. A. G. H. Smart, but Dr. Smart left for an U.N.R.R.A. appointment before the report was drafted.

The committee begins its report with a consideration of medical policy in the Colonies. The medical services in the Colonies are now generally regarded as part of a co-operative effort to improve the well-being of the community, and it is accepted that there should be the closest co-operation not only between the Government medical departments and the services provided by the local authorities, commercial organizations, and voluntary bodies, but also between medical workers on the one side and the staffs of the administrative service and of the education, agriculture, and veterinary services on the other. One point made is that hospital services in most Colonial territories can at present be available only to a small proportion of the people who are suffering from disease or its results. On the other hand, in tropical territories at any rate, much sickness is preventable. Thus it would appear that the primary aim of medical workers in such territories should be to improve health standards and to control transmission of disease.

In fulfilment of this medical policy nursing services have clearly an essential part to play. It is within these services especially that scope is likely to be found for the greatly increased employment of women as agents of health and welfare; and the expansion of health education and the welfare of mothers and children will largely depend on the work of nurses.

Standards of Colonial Nursing

In each Colonial territory or group of territories, in the committee's view, there should be set up machinery for the control of standards of nursing by means comparable with those adopted by the General Nursing Council for England and Wales and the Central Midwives Board. It is recommended that all trained nurses should be registered, and that the control of such registration, of nursing education, and of discipline should be in the hands of a Nursing Council set up in each territory or group of territories under a Nurses Registration Ordinance. A Midwives Council should also be established, though in some areas the two might form a joint body.

The committee deals first with locally recruited nurses. These should be trained in schools in their own territories, where the standard should be such as to render Colonial certificates acceptable to the General Nursing Council. After qualifying in these schools, nurses showing aptitude in administration or in special departments in their own territories should be given every facility for post-registration training in the United Kingdom or elsewhere. The "block" system of training is advocated under which the student is relieved of nursing duties in hospital for varying periods in each year and during those periods she receives her theoretical training. It is recommended that the complete period of training required for certificate should be four years, the first three years to be devoted to basic training, and the last year to any special branch.

Midwifery Service

The evidence given to the committee emphasized strongly the need for efficient midwifery service in the Colonies. The committee considers that the minimum period of instruction to qualify for registration as a practising midwife should be at least two years for those without a nurse's training and one year for nurses who have completed the basic three-year course. The aim of Colonial Governments ought to be to improve the training given in midwifery until it is comparable with that given in the United Kingdom, and the curriculum should stress health teaching in relation to pregnancy and the bearing of maternity work on other community welfare services.

It must not be supposed that the recommendations relate only to areas where education has reached school certificate level. The backwardness of girls' education is not in itself a valid reason for delaying the establishment of a nurses' training school, although the course of training will require modification. The teaching must be in a more simplified form; and, as a temporary expedient, in territories where two or more levels of general education exist among the population it is proposed that there should be two grades of certificates for nursing, the second to include the same subjects as the first but with a smaller content, and the precepts to be inculcated by practical demonstration rather than by lecture.

As for the training of nurses in the United Kingdom and Dominions for work in the Colonies, it is suggested that candidates should be registered in the general part of the General Nursing Council's register. Except for a few specified posts, candidates should also be State-certified midwives. Before appointment to the service they should have had at least one year's hospital experience after State registration. Sister tutors and midwifery teachers should be nursing sisters who already had had some Colonial experience. All candidates before taking up their appointment should be given a special course of instruction designed to equip them adequately for the Colonial Service, and they should set themselves to learn the principal language of the territory.

On the question of recruitment and conditions of service, it is suggested that the Colonial Governments should provide full information concerning local conditions and duties, and that more effective publicity might be given in the schools to the possibilities of a nursing career in the Colonies. Conditions of service should be at least as favourable, having regard to local purchasing power and taxation, as those already recommended by the Rushcliffe Committee for nurses in this country, pension arrangements should be not less attractive, and provision should be made for transfer of nurses between this country and the Colonies, in either direction, without loss of pension rights.

---

A PIONEER IN BLOOD TRANSFUSION

A fund the object of which is to raise a minimum of £10,000 for the development of blood transfusion and research in connexion therewith has been inaugurated in memory of Percy Lane Oliver, a pioneer who in 1921 brought together the first small group of blood donors and devoted his life to the blood transfusion service. Oliver was secretary of the Camberwell Branch of the British Red Cross Society when a message was received from King's College Hospital, which was anxious to find someone willing to give a pint of blood to save a dying patient. He called his associates together and persuaded them to leave in a body for the hospital as volunteers. The blood of each was tested, one of them was chosen, and the life was saved. Thereafter Oliver formed a small society of men and women who agreed to submit to blood tests and to "stand by" for any hospital call; this expanded into the London Blood Transfusion Service, and eventually was taken over by the British Red Cross Society. By the beginning of the recent war there had been recruited in London alone more than 3,000 donors, giving between them 10,000 blood transfusions a year. Oliver, who died in 1944, devoted his life to this organization. A committee has been formed under the presidency of Dowager Lady Ampthill, with Air Vice-Marshal Sir David Munro and Mr. Victor Riddell, F.R.C.S., among its members, to perpetuate his memory by raising a fund for research into matters relevant to blood transfusion, for the establishment and maintenance of voluntary blood donors' services, and for the giving of lectures and issue of literature. The address of the Oliver Memorial Fund is 18, Wilton Crescent, S.W.1.

MEDICAL STUDENTS' CONFERENCE

A clinical conference under the auspices of the British Medical Students' Association was held at the end of last month in the Leeds University Medical School; students from the Universities of Durham, Liverpool, Manchester, Birmingham, and Sheffield, and from London hospitals attended. Mr. George Armitage, F.R.C.S., honorary surgeon to the General Infirmary at Leeds, gave the inaugural lecture on "The Personality of a Hospital."

Mr. Armitage said that in the history of the Leeds General Infirmary the personality of the staff had always impressed itself upon the institution. He mentioned William Hey primus, pupil of the great John Hunter and one of the first four surgeons to be appointed to the Infirmary in 1767; Samuel Smith, who lectured in the medical school from 1831 to 1858; John Heaton, Pridgin Teale, Sir Clifford Allbutt, McGill, and in later years Lord Moynihan. There was also the influence of the medical student. The student body added that flavour which, to a hospital, meant life. A hospital was safeguarded, so far as its patients were concerned, if its workers came under a constant fire of criticism from watchful students. The personality of a hospital seemed to him its greatest asset, and this thought must quicken the sense of responsibility of all working in it and for it.

Col. Malcolm Stoddart-Scott, M.D. (M.P. for the Otley and Pudsey Division of the West Riding) gave a general lecture in which he discussed the moral and sociological problems connected with the declining birth rate.

OPENING OF MEDICAL SCHOOLS

WESTMINSTER HOSPITAL

Archbishop of Canterbury on Doctors and Priests

The inaugural address at Westminster Hospital Medical School was given on Oct. 1 by the Archbishop of Canterbury, Dr. Geoffrey Fisher. With him on the platform were the Lord Chancellor (Lord Jowitt), Lord Horder, Mr. H. S. Souttar (President of the British Medical Association), Lord Wigram (President of Westminster Hospital), Mr. Eardley Holland (President of the Royal College of Obstetricians and Gynaecologists), and Air Marshal Sir Harold Whittingham (Director-General, R.A.F.M.S.).

Dr. **Fisher** prefaced his address by making two general observations. The greatest need of this generation, he said, was an accepted doctrine of the meaning and purpose of life by which could be controlled the multiplicity of ideas, desires, and passions which poured incessantly over human activities. For a long time past two processes had continued side by side—the fragmentation of truth and the frustration of life. Fragmentation of truth had occurred partly because the field of human knowledge had extended so vastly that no man could cover more than a fragment of it, and the idea of truth as governing the whole disappeared; with this had come—probably as an effect following the cause—a sense of frustration. His second observation was that the remedy could be found only in a truth and purpose which was greater than man, not created by him, but governing and controlling him, to which he would give the name of religion.

The medical profession (Dr. Fisher continued) had its scientific, social, and personal aspects, and he desired to say a word on each. Its scientific aspect was the exciting and enthralling pursuit of truth, the acquisition of exact knowledge by experiment and observation. Scientific truth was discovered by man, not created by him. From the beginning of time penicillin and the atomic bomb were potentialities; man did not put them into the universe, and this compelled the reflection, How did the universe become such an ingenious thing as it was—by chance or by design?

Pure science was concerned only with truth and error, but as pure science it existed only in abstraction. As soon as it was applied and used, it inevitably became involved in another contrast—good and evil; that is to say, in moral issues. Medical science touched moral problems at a hundred points.

> "We laymen are liable to get frightened lest science by degrees deprive us of any right to exist. We long ago handed over our bodies to the medical profession, but our souls have now gone with them, and the psychologist tells us ghastly things about them—for example, that we do not exist, save as a series of reactions. It will not do. Man remains essentially himself in spite of all the things that science may find about the workings of his machinery."

The Key Position

Medical science, said the Archbishop, was a social science. It was the bounden duty of medical science to do its utmost for society, and of society to see that all the resources of medical science were freely open to all citizens. It was rather easy to get mesmerized by the word "social." It led one to think of men in the lump, and of health and disease in the lump, which was perhaps necessary for the purpose of statistics and organization, but mass thinking was always dangerous. If the individual was left out of sight society became a tyranny. The unit of society was the family, and the key position in the medical profession was the family doctor. Whatever specialization was otherwise required, the whole thing revolved around him. Here the speaker touched on the problems of marriage and sex, asking whether medical students were trained to give skilful, understanding, and wise advice on these problems instead of gathering their impressions from casual experience.

Finally he dealt with the personal aspect of medicine.

> "You doctors are with us priests in vindicating the value of the individual. Even in our civilized society there are incalculable forces to depress individual values. You in your profession go and serve the individual for what he is, at all costs to yourself, and your justification is in the end to be found only in the divine love repeating itself in human charity. For that reason you are never only doctors, but also priests in the true sense of the word. The doctor above all—except for the priest—must meet his work with this unity of doctrine about life which can give him a settled, wise, and competent manner of handling the problems presented to him. What patients look for is something stable in the doctor who ministers to them. They want to be sure that he has looked at life steadily and has seen it whole, and has in that process gained wisdom, or, as I should call it, the religious outlook."

The Archbishop added that he had asked a son of his, who was a medical student, what he was to say on that occasion, and his son had reminded him of a remark of Dean Inge that doctors on qualifying should be ordained to their ministry as much as priests. That was true, said Dr. Fisher, and he desired to give public notice that if a procession of students just qualified made their way across Lambeth Bridge and assembled in Lambeth Palace Chapel he would be only too glad, not indeed to ordain them, but in a suitable form to commission them for their ministry.

A vote of thanks to the Archbishop was proposed by Air Vice-Marshal **Stanford Cade**, and seconded by Dr. R. J. V. **Pulvertaft**. The Dean in his report welcomed back from the Forces six members of the teaching staff, but stated that there were eight vacancies to be filled, and the strain on the existing staff must continue until the best candidates were forthcoming, whether now in uniform or not. The Westminster Hospital School of Medicine welcomed and invited women students to join them once again. A number of prizes, medals, and an inauguration cup were presented to successful students, and a vote of thanks was accorded to Mr. A. W. Clowes, chairman of the medical school committee, who presided.

Opening the 104th year of the College of the Pharmaceutical Society of Great Britain on Oct. 3, Mr. J. C. Young, the president, said that in the coming session, and for the first time in the history of the College, the number of graduate and postgraduate students far outnumbered those taking the Ph.C. and C. & D. diplomas. This indicated the trend of pharmaceutical education, which was rapidly passing into the universities. He welcomed this, for the effect on pharmacy must indeed be beneficial. One could wish that all of them, no matter what branch of pharmacy they had decided to take up—whether retail, hospital, or manufacturing—should not be content with the C. & D. but would stay a further year, if at all possible, to take the higher qualification. He hoped also that many would aspire to postgraduate work and apply for one of the scholarships available.

HOSPITAL AND MEDICAL SCHOOL FOR UGANDA

An important step forward in the development of the medical services in East Africa has been taken in Uganda, where plans for the new hospital and medical school at Mulago, Kampala, are being made. A grant of £500,000 is provided for the purpose under the Colonial Development and Welfare Act. The designer is Mr. Rees Phillips, F.R.I.B.A., who was responsible for the big hospital at Carshalton, Surrey, and the new wing of the Brompton Hospital. He spent some weeks in Uganda and interviewed all officers now working in Mulago.

The new hospital to be built will provide accommodation not only for Africans but for Asians and Europeans, and provision will also be made for a large nurses' training centre to accommodate up to 700 nurses. The new medical school is planned to accommodate medical students up to an annual admission rate of 30, and there will also be accommodation for training pharmacists, laboratory assistants, and sanitary inspectors. The wards of the hospital will be small, the largest one holding 16 beds, and there will be a large proportion of single-bed wards. In the African section alone it is planned to provide at least six operating theatres equipped to deal with surgery of every kind.

The Friends Ambulance Unit was formed in 1914 by a group of Quakers. Until 1916 its members served as medical aid men with the British and French Armies on the Western Front. It was re-formed in 1939 by some of its earlier members. Although the work in Finland, Norway, Greece, and the Western Desert was in direct line with the tradition of the first unit, it has, since the days of the air attacks on London in the second year of the war, turned increasingly to the relief of the civilian victims of war, famine, and disease. It is now devoted entirely to this work, and 500 of its members are over-seas. A report of work done in Europe and the East in June, July, and August, 1945, has been published from 4, Gordon Square, W.C.1.

Correspondence

Housing and Health

Sir,—You have done well to publish Dr. H. Nelson's paper (Sept. 22, p. 395) as the profession is apt to overlook the close association of disease with poverty, although the facts are plentiful and well authenticated. But this association is partly casual, and we ought to try to distinguish the casual from the causal, as the remedies are different.

In the first place the standard of hygiene is much lower among the poor, and this accounts for a good deal of disease. Fresh air is nearly always lacking, and infants are the greatest sufferers. It is common to see them in their prams with the hood up in the darkest corner of the overheated living-room; very often they are not taken out for days on end in the winter. Professional people (in these days) invariably keep their infants out of doors all day, and it is a fact that their children suffer and die from catarrhal diseases far less frequently than poor infants.

Discipline.—On the whole the wealthier classes discipline their children better (or pay a nurse to do it) than the poorer classes. They enforce early bed, if for no other reason, because after listening to their prattle all day they are glad to get a little peace for themselves in the evening. Many poor people start wrong from birth by keeping their infants downstairs with the lights blazing, the wireless blaring, and everyone smoking until they themselves go to bed; then they wonder why they cannot get their children of 6 to come in from the streets till a late hour. This problem simply does not arise with the rich. *Waste.*—The poor are proverbially wasteful, and one has only to glance at the pig bins, which are nearly always on their sides, to see this. At the height of the siege of Britain I used to see half-loaves of bread which had been thrown away.

Unwise Spending.—It is not uncommon for working men to admit to me to spending 15s. to £1 per week (£40 to £50 per year) on cigarettes. The cinema twice a week is practically a necessity to many families. I do not know what is spent on drink and betting, but the "football pools" are widely patronized. There is no doubt that the standard of living could be appreciably raised by the exercise of reasonable economy, and one does see many families who are economical and are far better equipped as a result. *Neglect.*—Every experienced G.P. will recollect cases where he was called in at the last minute to sign a death certificate for a moribund child when he was in two minds whether to inform the coroner, and others involving a high degree of ignorance and folly. They may not be very common, but they do push up the infant mortality rate, and I have never known or heard of them in the well-to-do. Social pressure is too strong to permit that sort of thing.

Malnutrition.—The first essential in guarding against this is reasonable table discipline. Many children have to be pressed (I do not say coerced) into eating fat or green vegetables, and prevented from eating the wrong things or between meals. The war has probably done good to nutrition by limiting sweets, and it is likely that excess of sugar prevents the absorption of other essential foods. It has also taught us what a lot of food we can provide for ourselves. It requires no great skill or knowledge to keep chickens, and experience shows that they lay perfectly well when fed on potatoes and balancer meal; and their excreta can be used on the compost heap. It is no superhuman task to grow enough vegetables for a household of ten to have greens or roots nearly every day of the year. It is sad to see how many allotments have already been given up, and it is surely not unreasonable to encourage people to help to feed themselves, especially if they are unemployed.

It is impossible within the limits of a letter to touch on remedies, but if a correct diagnosis is made these will often suggest themselves. Suffice it to say that there is a big harvest of health to be reaped without any new discoveries by applying money and ingenuity to judicious educational propaganda.—I am, etc.,

Norwich. FREWEN MOOR.

Psychiatry in the Army

Sir,—I shall be interested to hear the views of others concerning the part that psychiatry has to play in the disposal of many cases which come under the review of a Service doctor and which are not dealt with by specialists in other branches of medicine. To send a patient to the neuropsychiatrist is frequently the refuge of the diagnostically destitute, the results, in my experience, often being most disappointing. I refer to those cases which present certain well-known features, such as headaches, dizziness, lack of confidence, depression (with or without suicidal tendencies), lack of emotional control, temperamental instability, vague muscular pains, insomnia, bad memory, and multitudinous digestive disorders, coupled with inability to carry out their appointed duties. Having received a clean bill of health from all other specialists they are handed over by the unit medical officer in desperation to the neuropsychiatrist for diagnosis and disposal. The neuropsychiatrist will in most cases extract a typical history, including many, if not all, of the following features: nail-biting, childhood bed-wetting, fear of the dark, anorexia and insomnia, functional impotence, and, in some cases, upset over domestic or Service matters.

The first step on the downward path is now taken. A diagnosis of anxiety state is made, the medical category is lowered, and the patients' oversea service is restricted. Almost without exception on returning to their unit they deteriorate steadily, until, in desperation, the final scene is enacted, and they are invalided out. I contend that this course is unsatisfactory and immoral. The patients' weaknesses, whether real or alleged, are pandered to, and a chronic state of neurotic invalidism is engendered, which makes them a burden to all concerned, including themselves.

A unit medical officer can observe these cases between the time they are told they will be invalided and the date of their actual discharge. What a transformation we now behold! The lame leap for joy, the blind see, and dyspeptics eat large indigestible meals without apparent discomfort. Why this miraculous change? What healing balm has been applied? What unction bestowed? In my opinion these people have, by conscious or unconscious deception, achieved their object. Instead of uniform they will wear civilian clothes; instead of a barrack-hut, the comforts of a home; instead of discipline, independence. I will quote a few examples of many that I have seen personally. An N.C.O. at one time quite incapable even of light duty is now running a large greyhound business with great success (and commensurate profit). A girl who could hardly walk from exhaustion and fatigue now does a heavy day's work as a civilian waitress (on excellent pay). Another N.C.O., who had outbreaks of weeping on being asked to work overtime, now he knows he is to be invalided, can be seen merrily cycling home five miles to work in his garden.

I have become very cynical of such cases. I feel that many of them think that if they make life sufficiently intolerable for their colleagues and the medical officer they will attain their object—as in many cases they do. The melancholy results obtained are not the fault of psychiatrists, unit medical officers, or the executive, but of a system which permits this escape mechanism for those unwilling to bear the heat and burden of the day—a system which lays too much stress on psychological illness and not enough on a man's responsibility to his fellows. Previously such patients had my sympathetic attention, but now I refer more and more cases to the executive for disciplinary action, with the most surprising and gratifying results. In a recent case of a senior N.C.O. dealt with in this manner he decided that hard work was more acceptable outside prison than inside.

I shall be interested to hear the experience and opinions of others on the subject.—I am, etc.,

KENNETH G. BERGIN,
Inverness. Wing Cmdr., R.A.F.

Penicillin and Synthetic Rubber

Sir,—I should like to reinforce the warning given by Mr. F. A. R. Stammers (Sept. 22, p. 400) against the use of synthetic rubber in apparatus for the administration of penicillin. In an experiment in which a weak solution of sodium penicillin was enclosed in sterile lengths of synthetic and natural rubber, and in glass, and kept at room temperature overnight before assaying potency, the following results were obtained:

Penicillin Solution	Zone of Inhibition of Growth of "Oxford" Staphylococcus on Seeded Agar Plate
In contact with glass	15 mm.
In contact with natural rubber	13 mm.
In contact with red synthetic rubber ..	3 mm.

It will be seen that an almost complete loss of potency occurred in the penicillin solution that was in contact with synthetic rubber. The fact that even a natural rubber has some destructive effect upon penicillin emphasizes the need for an administration apparatus which will not require the lengths of tubing used in so many current designs.—I am, etc.,

E.M.S. Hospital, Bridge of Earn. M. E. Morgan Thomas.

Fenestration for Otosclerosis

Sir,—Your leading article on this subject (Sept. 29, p. 430) will be the focus of attention of all who have the care of these tragic cases of otosclerosis. This common disease, from the ravages of which no adolescent or adult is exempt, develops so insidiously and bilaterally that the deafness is far advanced when the patient first seeks advice. (I have yet to encounter an early case of otosclerosis.) By this time the patient is already doomed to an insidious progressive bilateral incurable deafness, which will result, with the passage of years, in a complete loss of hearing for air conduction. Otosclerosis is by far the commonest cause of an insidious bilateral deafness developing in adolescents and young adults, and is especially prone to attack young girls with otherwise unblemished health. The possibility of relief by the fenestration operation brings a ray of hope and even opens up the vista of a cure. I write to plead for the early establishment of many suitable centres in London, solely devoted to these operations; at present such facilities are meagre, if they exist at all.

Some three years ago I was consulted by an otosclerotic of about 35 who was so deaf that only a very loud shout bawled into his ear could be perceived. Tired of years of ineffectual visits from hospital to hospital he demanded that something be done for his deafness. While the audiometer revealed a bilateral loss of 60 to 70 decibels for all tones for air conduction, his hearing by bone conduction (as is usual in these conditions) remained good. I performed a fenestration operation on his labyrinth (operation time, 90 minutes) without the use of a cartilaginous spigot. The result was dramatic and exceeded all expectations. The patient could hear ordinary conversation easily at over 15 feet. Now, years later, he can still hear an ordinary conversational voice effortlessly at 8 to 10 feet, and has permanently discarded his bone-conduction instrument without which he had (previous to the operation) been unable to hear at all.

The success of this case demonstrates the miraculous and sustained restoration of good hearing to the completely deafened person—one who has invariably been told that nothing can be done for him.

Any patient suffering from advanced otosclerosis (with an air-conduction loss of more than 40 to 50 decibels) should have the opportunity of undergoing, if he so desires, the operation of fenestration of the labyrinth. The exact degree of deafness must first be ascertained by testing with the audiometer for air and for bone conduction. If the bone conduction is uniformly satisfactory there is a good possibility of the hearing being restored by operation, the exact extent varying from case to case. My operational experience bears out the statement that if the bone conduction for the high frequencies is poor the deafness is unlikely to be alleviated by the operation. I can also confirm the statement in your leader that the fenestration operation slows the progress of the disease on the operated side, the patient depending on this ear for all residual hearing at a time when the air conduction of the unfenestrated ear has been completely lost. In one case under my care the fenestration operation had been undertaken in France over 8 years ago. Loud conversational voice could be heard at up to 3 feet by the fenestrated ear (the fistula test being still positive), whereas the other ear was completely deaf.

The fenestration of the labyrinth is performed in one stage. The operation presents no undue difficulties; nor need it be unduly tedious, certainly not to the experienced mastoid surgeon supplied with adequate and trained assistance and with suitable equipment, particularly an electric bone drill. Average operation times vary from 60 to 90 minutes.

Your leader omits reference to the distressing vertigo following the operation—vertigo which may last for many weeks or even months, delaying convalescence. Tinnitus may also be troublesome. The spectre of a facial-nerve lesion resulting from the operation is one that always looms large before the surgeon—a spectre in no way diminished by the fact that nearly all the cases suitable for operation develop in handsome young females. However, one can avoid injury to the nerve, and in all my experience only one case developed, 3 weeks after the operation, a slight facial paresis which resolved in a few days.

The difficulties encountered are not only those associated with the actual fenestration. There are those of getting suitable equipment these days and of lack of suitable surroundings in which to undertake the operation, which is a "clean" one. The patient should be hospitalized in surroundings consistent with this type of operation, one in which the entire success depends on securing and maintaining freedom from infection and obtaining primary healing. There is no place where the risk of infection is greater than in the crowded wards of an ear-nose-and-throat hospital or department. This is a pity and a great handicap, as the special hospital is the place *par excellence* for the performance of this delicate operation. One may express the hope that in the new oto-rhinological era at the Royal National Throat, Nose, and Ear Hospital, which will rise phoenix-like from the ashes of the Central London Throat, Nose and Ear Hospital and the Golden Square Hospital, special wards will be set aside devoted solely to the fenestration operation for the relief of deafness due to otosclerosis, and that the scale will be of the same magnitude as that now undertaken so successfully in the clinics of the U.S.A.—I am, etc.,

London, W.1. N. Asherson.

Sir,—I read your leading article on this subject with great interest, and I admired the well-balanced exposition of a procedure which, though it "has passed the experimental stage," is still in the dawn of its usefulness. It is, therefore, with the greatest respect I would differ from the writer on a few points. I do not think the operation need be "long and tedious," nor need it "remain in the hands of a few with special aptitude." I believe it to be easily within the ability of any competent aurist who will study the anatomy and the technique. Actually, in my experience, the most difficult part of the operation is not avoiding damage to the facial nerve but the fitting of what Lempert calls the "stopple" of cartilage into the artificial opening of the canal, and this difficulty is one of instrumentation and only awaits the freeing of our surgical instrument craftsmen from other duties. There can be no doubt that if the war had not adversely affected the hospital facilities in our large cities we should now possess a fuller knowledge of the scope of this operation. As it is, we owe a great debt to Lempert and his colleagues for showing us the possibilities of an outmoded surgical procedure vitalized by modern technique. I am sure that not only has the operation come to stay, but in the near future its scope will increase and the operation be performed for types of deafness other than otosclerosis. A large field of investigation is opening up, and this is a field which the aurist returning from active service can enter on equal terms with his more fortunate colleagues.—I am, etc.,

London, W.1. Edward Carew-Shaw.

Sir,—I read with interest the leading article on fenestration for otosclerosis. As you remark the operation has now passed beyond the experimental stage and come to stay. Having recently had the privilege of working with Lempert in his clinic in New York and of closely observing his results and those of other leading aurists in other New York hospitals who are also performing the operation, I am in the position to confirm this. Discussions of the value of the operation with both the patients and the surgeons lend support to this view. I myself have worked on this operation since 1937, and it is gratifying to know that it is now being accepted.

The procedure is long, slow, and difficult, and the slightest deviation from the principles of Lempert's carefully planned technique is liable to result in failure. I was fortunate to witness Lempert perform a "revision case," where a cartilage stopple had been inserted into the fenestra 15 months earlier. On lifting the epithelial flap the cartilage stopple was found to be freely mobile. The cartilage was removed for microscopical study and a fresh one inserted. In your leading article you remark that "since the stopple is squeezed into the opening like a cork it is difficult to understand how it retains the necessary mobility." This is a misconception; the stopple is not squeezed into the fenestra but rather laid in the opening, where, being cone-shaped, it is supported by the shelving sides of the aperture and retains free mobility. My own results have so far also borne out the advantage of using the stopple as against the earlier methods in which it was not used.

One seldom finds a patient who regards his hearing aid as anything but a tiresome necessity, and most of them feel that to regain hearing to a level sufficient to be able to dispense with the aid makes operation worth while. Apart from the rather complicated technique requiring trained assistants, the most important factor still remains the careful estimation of the remaining cochlear function. It should be borne in mind that otosclerosis also occurs in cases which may have had otitis media. This latter disease if completely resolved does not necessarily debar the patient from benefiting from the operation.—I am, etc.,

London, W.1. E. R. Garnett Passe.

Risks of Gastroscopy with the Flexible Gastroscope

Sir,—It is with great interest that I read the article by Drs. C. M. Fletcher and F. Avery Jones on the risks of gastroscopy with the flexible gastroscope (Sept. 29, p. 421). I, personally, experienced a similar fatal case about two years ago. Although this article should be of considerable value, especially to those whose enthusiasm for this kind of examination rather overshadows their experience, I would nevertheless like to add that in my opinion there are definite causes that contribute to these mishaps, and there are certain features about these patients and methods of procedure which, if considered, should go a long way to minimize this small but most disconcerting risk.

The three cases quoted by Drs. Fletcher and Avery Jones were in elderly women; my own case was in a woman of 63 years, and the perforation also occurred within the upper 1½ inches of the oesophagus. If one considers the normal anatomy of the oesophagus it will be recalled that the musculature posteriorly is deficient in the upper 1½ inches, there being a dehiscence of the inner longitudinal fibres, and the gap thus left is covered only by the circular fibres. The mucosa, like that of the stomach, tends to atrophy with age, especially in women; if this atrophic change occurs in the upper end of the organ an area exists which may be particularly vulnerable and liable to injury or perforation.

The tendency for many gastroscopists is to extend the head too much during introduction of the instrument. The upper end of the oesophagus becomes stretched over the bodies of the 6th and 7th cervical vertebrae and its posterior wall lies in direct contact with them, and, in the presence of an atrophic mucosa, the impact of the metal tip of the gastroscope may be sufficient to start a small tear; subsequent pressure on the delicate area by the rigid portion of the instrument against the bony background with the head fully extended would increase the damage already inflicted. Another important point is that it is impossible to obtain a circular field of vision or to visualize fully certain areas in the kyphotic subjects, and it is a great temptation to the operator to keep on extending the head in order to increase the field of vision. In these circumstances undue pressure of the rigid portion of the instrument may cause a small burst rather than a tear in the atrophied mucosa; in this type of patient the instrument is frequently passed with ease, no injury being produced during introduction. Following upon my own mishap, I always introduce the instrument with the head slightly flexed, gradually extending the head as the rigid portion passes; in addition I find that the rubber finger-tip fitted to my Hermon Taylor gastroscope is a great help in negotiating the crico-pharyngeal sphincter and the hypopharynx.

I feel convinced that if the operator is acquainted with the above anatomical and pathological points, and exercises care in introduction, even in the types of cases mentioned, the risks associated with the use of the gastroscope are really no greater than those during bronchoscopy or other endoscopic examinations.—I am, etc.,

London, W.1. Harry Freeman.

Sir,—The article written by Dr. C. M. Fletcher and Dr. F. Avery Jones on the dangers of gastroscopy brings a timely warning. There is a danger that the practice of gastroscopy may be brought into undeserved disrepute if it becomes a weapon of "the occasional gastroscopist." It is still thought that gastroscopy is as easy as cystoscopy or oesophagoscopy, and that the gastroscope can be passed after reading about it or watching an expert on a few occasions.

Fletcher and Avery Jones with their vast experience show clearly how dangerous the instrument can be, even in expert hands. In my opinion they have, however, failed to emphasize sufficiently the fact that under no circumstance is force to be applied in the passage of the instrument. If the instrument sticks in the hypopharynx or in the region of the cardiac orifice it should be withdrawn slightly and another attempt made to pass it on. If it persists in sticking, force will then cause it to pass but at the expense of severe damage to the oesophagus. If the obstruction is due to spasm, waiting for half a minute and then attempting gently to pass the instrument will often succeed. If a second attempt fails, then, in my opinion, it is unsafe to continue and the manœuvre should be abandoned.

It should be borne in mind that cases occur where it is impossible to pass the instrument owing to spinal curvature or other physical abnormalities, and, while I would not go so far as to say that gastroscopy should not be attempted in these cases, I certainly would emphasize that if it is attempted not the slightest force should be employed, and that one should be prepared for complete failure. Both the Wolf-Schindler and the Hermon Taylor gastroscopes are composed of a flexible tube attached to a rigid one. Nobody would dream of passing an oesophagoscope except under direct vision, but in gastroscopy a semi-rigid tube is passed blindly. Surely in such a case no force dare be applied.

Again I deprecate the large out-patient gastroscopy clinics where patients undergo gastroscopy and are allowed to go home very soon after. Perhaps the only excuse for the out-patient gastroscopic clinic is the shortage of beds. I have made a practice of keeping every gastroscopy case in hospital for 24 hours before discharge, and though, after nearly 500 cases, I have not had a single mishap, Fletcher and Avery Jones have clearly shown that gastroscopy, like cystoscopy, is not without its dangers. Schindler has emphasized how necessary it is for the complete general examination to be made of the gastroscopy patient. This should include the spine, chest, abdomen, and throat. All my cases receive this examination, and a careful anamnesis has saved me twice from passing this instrument on epileptics. There is also the nervous, unstable, and unco-operative individual who may easily convert his examination into a catastrophe.

Gastroscopy in the edentulous, big-mouthed individual is very easy, and is apt to mislead the novice. When the opposite type of case is attempted the experienced gastroscopist knows when to desist. It is said that the good surgeon knows when not to operate, so the good gastroscopist should know when not to persevere in his attempts to pass a semi-rigid tube blindly.—I am, etc.,

St. Mary Islington Hospital,
London, N.19. I. I. Price.

The Operation for Varicose Veins

Sir,—The comparatively new operation of ligature and injection of varicose veins is steadily becoming established. Long-term results come forward slowly, because a period of three to five years must elapse before each step can be evaluated. From time to time further points arise, and it is therefore necessary for those who have worked, talked, and written on this procedure to "pool" the information as it comes to hand. In the *Journal* in December last (1944, 2, 814) I advocated the operation of ligature and injection at the groin and ankle. I would like to report several items which have come to my notice in connexion with this operation.

1. *Post-operative Painless Haematuria.*—The operation is occasionally followed by painless haematuria; I know of five cases. It follows in twenty-four hours. Sometimes blood appears at one or two acts of micturition; at others, throughout the day. Another surgeon has told me of a similar case. It has followed the injection of 30% saline and also of ethamolin. There were no further ill effects.

2. *Ligature and Division of the Internal Saphenous Vein in the Groin.*—In ligaturing the internal saphenous vein in the groin it has been the custom to tie the lower end of the vein once but doubly tie the upper end. I have seen the ligature on the lower end slip. It was caused by the bursting effect of the

injection of 20 c.cm. of 30% saline at the ankle. It would appear necessary to transfix both divided ends of the internal saphenous vein in the groin when it is injected at the ankle, and to make the upward insertion slowly. Further, a large excision must always be made to ensure that the internal saphenous and its branches is tied and to avoid ligature of the femoral vein or even of the femoral artery.

3. *External Saphenous Incompetence.*—With regard to incompetence of the external saphenous vein, it is at times seen without the internal saphenous vein being apparently affected. Follow-ups have shown that if the external saphenous vein is ligatured and injected at the popliteal space and the internal saphenous vein not treated, then later on the internal saphenous vein becomes affected and needs ligature and injection. Therefore, it is probably right to ligature and inject the internal saphenous vein in all cases of varicose veins where there is incompetence of the external saphenous vein or of the communicating veins.

4. *Subsequent Injections.*—Occasionally, after the remedy of ligature and injection at the groin and ankle, one or two lengths of vein remain unsclerosed and these require subsequent injection. I use ethamolin for this, and the amount needed is 1 or 2 c.cm.—larger doses tend to be followed by gross, painful, and temporarily incapacitating reactions. The ethamolin should be used from ampoules and not from a rubber-capped bottle.

5. *Pulmonary Emboli.*—I am aware of this occurring in two patients in a series of 570. One caused an illness of six weeks; another for ten days. Doubtless, there may have been other instances. The preventive measure seems to be scrupulous aseptic technique and to get the patient out of bed the day of operation. The operation is a major procedure: minor operating-theatre technique is dangerous. When the veins are gross in both legs then only one leg per session is advisable.

6. *The Scars after Ankle Incisions.*—With regard to the procedure of ligature and injection at the ankle, it is proper to mention that the scar for a few weeks is visible through silk stockings, and here again lies the need for accurate closing of the wound to avoid "eyesores" and disrepute to a first-class operation.

7. *Deaths after Operation.*—Dr. Foote recently reported a death following the operation of ligature and injection of varicose veins, and in a personal communication told me of his knowledge of it in the practice of other surgeons. So far it has not occurred with me, but doubtless I have only to keep on doing the operation before I have the experience. Knowing this, therefore, remarks on the prognosis of the operation must be appropriately expressed.

Finally, I would urge the necessity for giving full time to the operation; it is more than a minor procedure—one leg may take twenty to forty-five minutes, but the sessions are richly rewarded by the improvements bestowed on patients.—I am, etc.,

London, W.1. HAROLD DODD.

Anaesthetic Risks

SIR,—I so generally agree with what Dr. John Elam writes about anaesthetics that I have no difficulty in keeping quiet about it. His last letter (Sept. 22, p. 402), however, contains a deduction from Major Kremer's report on meningitis following spinal analgesia that seems to me unjustified, and—in so far as Dr. Elam's writings influence action, and that may be considerably—misleading. Here is the deduction: "After the publication of Major Kremer's report ... it will be clearly unjustifiable to use spinal analgesia for operations which can properly be performed under inhalation anaesthesia." Why? Because some serious complications followed spinal analgesia under certain circumstances? But complications are not confined to spinal analgesia. We have heard of delayed chloroform poisoning, though rarely of "ether" convulsions following ether and local anaesthesia; of sepsis, gangrene, and death following intravenous anaesthesia; of insanity following gas-and-oxygen; and of innumerable deaths for which no reasonable account was forthcoming following avertin.

What were the circumstances under which these meningeal complications took place? (1) In the Middle East; (2) all but one followed the injection of more than 10 c.cm. of nupercaine; (3) the "sterile" water in which syringes that had been kept in spirit were rinsed was not sterile. What does Major Kremer say about this? "It should be possible to avoid these unhappy cases completely." And again, "Probably the most convincing evidence in favour of the infective theory is the cessation of fresh cases with the tightening up of the aseptic technique." It would seem that it is easier to maintain asepsis here than in the Middle East. In more than 8,000 cases of spinal analgesia there has not been one case of meningitis.

The advantages of spinal analgesia are so great that it is desirable to spread the knowledge and practice of it. Here are some of them. (1) It is the least toxic of all the anaesthetics; when absorbed into the blood the ratio of the maximum clinical dose to the minimum lethal dose is of the order of one to ten. (2) It produces greater muscular relaxation than any other anaesthetic. (3) It prevents neurogenic shock. Because of these qualities it renders the performance of all operations requiring muscular relaxation easier, therefore quicker, therefore less liable to infection. In the case of abdominal sections the handling of the viscera can be much gentler; there is no need for powerful retractors; hence distension and discomfort are lessened and convalescence pleasanter and more rapid. It is the best anaesthetic for orthopaedic work on bones below the diaphragm because it prevents pain impulses from reaching the brain. The sum total of all these advantages cannot but help to save lives and lessen morbidity, though it is not easy to put this in statistical form. Inhalation anaesthesia acts by interfering with and to a greater or lesser degree damaging the cerebral cells.

Let me end on a note of agreement. Dr. Elam says: "Spinal analgesia should be administered only by the full-time professional anaesthetist, thoroughly familiar with the technique and aware of the many possible dangers." No one should give a spinal anaesthetic until thoroughly trained not only in methods but in the possible consequences and how to deal with them. In other words, it requires a thorough understanding of the physiology of spinal analgesia and temperament that remains cool and efficient in emergencies. The responsibility of the anaesthetist is more immediate with a spinal than with a general anaesthetic, and seeing he is dealing with a conscious patient the demand on his powers is greater. There is no doubt of the benefit to the patient in suitable cases.—I am, etc.,

E. FALKNER HILL,
Lecturer in Anaesthetics,
University of Manchester.

Continuous Pentothal

SIR,—The *Journal* of Sept. 1 (p. 289) contains a description by Dr. Marcus Bird of another "simple apparatus for continuous pentothal." It is well known that the ingenuity displayed by anaesthetists in inventing new pieces of apparatus and new and complicated ways of doing a very simple job is a source of constant amusement to many surgeons, and the considerable amount of space devoted in the medical press to descriptions of elaborate machinery for giving continuous pentothal would certainly seem to justify the surgeons in enjoying their joke. No doubt before very long the forces of atomic energy will be unleashed in the noble cause of assisting the anaesthetist to inject pentothal into a vein.

May I submit that in spite of the useful properties of bicycle valves, glass viewers, spring tool-clips, and long lengths of rubber tubing, the best method available for continuous pentothal is still the syringe and needle, and that if such simple equipment is inadequate use may be made of two syringes and perhaps two needles. The tendency for blood to clot in the needle is undoubtedly one of the conditions that tempts the modern anaesthetist to invent an elaborate piece of apparatus (and in describing it to condemn all other forms of apparatus because they are so complicated). If, however, a wide-bore needle is used and if it is not allowed to remain full of blood it may be left in the vein with very little risk of becoming blocked. The following method has been used again and again for operations such as herniotomy, meniscectomy, craniotomy, and even thoracotomy, and requires no apparatus whatever apart from syringes and needles.

The arm is placed at right angles to the body on a pillow on an instrument table (a Mayo's table does very well), and anaesthesia is induced with a 10-c.cm. syringe containing 5% pentothal and fitted with a smallish needle. I prefer a Luer-Lok syringe with a size 20 needle. Before the surgeon is permitted to start, even if the patient has not received the whole of the contents of the syringe, another syringe is taken, this time a 20-c.cm. for preference with a thicker needle. A Luer-Lok two-inch needle, size 18, is suitable. The needle can be inserted into the same vein as that already used, and the syringe is then secured to the forearm by a piece of "elastoplast" and the patient's wrist is bandaged to the table in case he lightens and tries to bend up his elbow. It is a great advantage to use, if at all possible, a vein an inch or two distal to the bend of the elbow, as the needle is then less easily dislodged and the syringe can be more readily strapped to the forearm in the correct position. When the syringe is empty it can be removed from the needle without dislodging the latter, especially if a long needle is used. If the arm is very slightly tilted upwards so that the antecubital fossa is a little above the level of the heart the tendency for blood to flow back into the syringe will be obviated, and the needle will normally remain full of pentothal and so be less likely to become blocked.

The method I have described can be combined with inhalation anaesthesia very easily if desired, and most of the time the anaesthetist can be sitting in his usual position at the head of the table. It takes only a moment to change the syringes. The patient is spared unnecessary discomfort if a small needle is used at first, but the use of a really large needle afterwards prevents blocking of the needle and spares the anaesthetist the necessity for using elaborate apparatus to prevent it from blocking.

Surely it is time that anaesthetists diverted their energy into more original and profitable channels and carried out the simple process of giving continuous pentothal in the simple manner that is so readily available to all who are prepared to put a needle into a vein and then inject pentothal down it, as and when necessary, with nothing more ingenious than one (or two) syringes.—I am, etc.,

J. D. Laycock,
Major, R.A.M.C.; Anaesthetic Specialist.

Blind Intubation

Sir,—I have just seen Mr. Hamilton Bailey's plea (Sept. 29, p. 440) for block anaesthesia in dealing with cases of Ludwig's angina. I think it worth while to mention the method of blind intubation in the conscious patient, the tube being passed after the nose has been sprayed with cocaine, further cocainization of the pharynx and larynx being achieved via the tube itself. Once the tube is in place, the operation can be performed under gas-and-oxygen anaesthesia, and the tube left *in situ* until the patient is again fully conscious. With this method there is no anxiety about the airway, and it can be performed by anyone with a knowledge of the technique of blind intubation.—I am, etc.,

John L. Insley.

Anaesthesia in Threatened Obstruction of Air Passage

Sir,—I have read with interest Mr. Hamilton Bailey's letter (Sept. 29, p. 440) on the question of the administration of gas–oxygen anaesthesia in cases of acute inflammation threatening obstruction to the air passage. Although I have had very little experience of cases of Ludwig's angina I have treated, on numerous occasions, acute inflammatory swellings round the pharynx, deep pharynx, and larynx, which have required surgical intervention. There is a certain amount of risk of obstruction arising even if only local anaesthesia or regional block anaesthesia is employed. If before administering gas–oxygen anaesthesia an airway is passed between the teeth, or a small wedge of rubber such as dentists use placed between the molar teeth, it will always be possible to direct a laryngeal inspection tube. It is not usually possible to insert a mouth airway owing to trismus or faucial inflammation, but it is always possible to put something in to keep the teeth from getting into contact. This form of treatment is, of course, conditional on the fact that the anaesthetist is fully acquainted with laryngeal and tracheal intubation.

The chief reason for my bringing up this question again is to draw attention to the fact that in my opinion all specialist anaesthetists should be thoroughly trained in direct laryngoscopy and bronchoscopy during operation within and around the air passage. I always feel much happier if I know that in an emergency I can call for an endoscopy set to be brought to me in a few seconds (suction should, of course, always be available). I cannot help thinking that many anaesthetic fatalities could have been avoided in the past, even where the operation for which the anaesthetic was given had no direct relation to respiration. The technique of laryngoscopy and bronchoscopy, especially the former, is not very difficult to learn.—I am, etc.,

London, W.1. D. F. A. Neilson.

Diiodo-hydroxyquinoline in Lambliasis

Sir,—The detailed report of Air Cmdre. T. C. St. C. Morton (June 16, p. 831) points to the successful use of diodoquin in cases of amoebic dysentery, particularly recommending this principle in view of its many advantages. The author points out that diodoquin has no effect on lamblia, and I should like in this connexion to refer to two cases which were treated successfully, and which are worth while mentioning as they did not tolerate atebrin—i.e., the lamblia resisted atebrin.

Case 1.—A geologist, 38 years old, suffered from diarrhoea. On examination it was found that it was caused by lamblia; he was treated with the usual method of 3×0.1 g. atebrin for five days. The attacks of diarrhoea became numerically less, but did not cease completely, and examination of the stool 10 days after completion of the atebrin cure again showed free lamblia and lamblia cysts in an abundant quantity. Diiodo-hydroxyquinoline was therefore prescribed in a dosage of 5 tablets a day for 10 days. The remarkable result was that the diarrhoea stopped within two days, and a stool examination immediately upon completion of the treatment yielded negative results. The patient has been free of complaints for more than a year now, and a recent examination of the stool did not show any lamblia.

Case 2.—A woman teacher, aged 25, who frequently suffered from spastic attacks in the right upper quadrant of the abdomen, was operated on, as *x*-ray examination showed the presence of gallstones. The attacks were thus eliminated, but periodical diarrhoea set in, which did not react to the usual therapy. An examination of the duodenal juice showed free lamblias. A test with the usual atebrin cure could not be made, as atebrin was not on the market at that time. Diiodo-hydroxyquinoline, as in Case 1, 5 tablets a day for 10 days, was therefore prescribed, with striking results, for the subjective complaints as well as the lamblia ceased to exist.

I suggest that the success of the lamblia treatment may depend on the quantity of diiodo-hydroxyquinoline administered. It has, in any case, been astonishing how promptly the desired effect set in in the two cases mentioned above.—I am., etc.,

Jerusalem. L. Schindel.

Perspex in Orthopaedics

Sir,—The article on perspex in orthopaedics (Sept. 29, p. 423) is interesting, but I should like to suggest that the authors have taken great pains to produce a plastic shell which is not as satisfactory as the plaster-of-Paris shell they use as a model. The authors list many advantages of perspex but fail to utilize them, the most important presumably being the waterproof nature of perspex, a property which can be given to plaster by means of varnish or a local waterproof shield. The other advantages are not utilized. Nobody can say the method of blowing the shell is quick or easy; the permeability to light is destroyed by the fact that condensation makes an absorbent lining essential to prevent the skin becoming sodden; and a non-ambulatory patient will not worry about the saving in weight.

I draw attention to this matter as I hope the use of perspex and allied plastic material will not be discredited by its employment in unsuitable cases. We must use the advantages to the full and avoid using this new material just because it is new and intriguing. Perspex scores on the following important points: (1) Lightness; (2) permeability to *x* rays; (3) local alterations by moulding are allowed throughout the course of treatment. In spite of what Scales and Herschell say, moulding is not easy and is a waste of time and material for short-term cases. To conclude, perspex is at present a useful expedient in many cases while a suitable "spread-on" type of plastic is being developed. It is not a universal replacement for plaster-of-Paris and should be employed only where its advantages are utilized, such as in the splinting of peripheral nerve palsy and the fractured burnt extremity.

Regarding the processing of perspex, I gave a few hints in the *Lancet* of June 26, 1943 (p. 803), and *Journal* of Feb. 12, 1944 (p. 236).—I am, etc.,

A. MacGowan.

Experiences of a Medical Prisoner of War

Sir,—As I was one of the British M.O.s at Torun for 3½ years, may I be permitted to offer a postscript to Dr. B. Markowski's interesting article (Sept. 15, p. 361).

When British doctors were allowed to go to Stalag XXA in 1940, all the sick who had been treated by the Polish M.O.s until then were unanimous in praise of the devotion and skill with which they had been helped. Everything possible was done for the sick, despite desperate lack of drugs, instruments, and sick accommodation. After those grim early days conditions improved very much. Fort XIV remained a hospital, but most of the patients were moved into huts at ground level, and continuous pressure on the German authorities produced other improvements.

With regard to the treatment of Russians, Dr. Markowski's article hardly does justice to the atrocious conditions under which they—died. His estimate of an 80% mortality is probably true. I know that in the one month of November, 1941, out of one fort of 1,200 Russians, 270 died. The fort had been overcrowded a few months before, with only 300 British prisoners! When I arrived at Torun the diphtheria epidemic had run its course and two wards full of paralyses were left. All these showed eventual complete recovery.

Apart from very early days, starvation was not seen among British P.o.W.s in this area, except those who had been confined in the notorious military prison at Graudenz. An interesting point about the latter was that men who had been there for three months were in a much worse condition than those who had served sentences of several years. The long-term prisoners appeared to become adjusted to the insufficient ration. Unfortunately complete notes on about 100 of these cases were removed during a search and not returned: evidence of this character was never popular in Germany. Differential treatment of P.o.W.s was marked. The treatment of "Badoglio Italians" in 1943 was almost as bad as that meted out to the Red Army in 1941.

Among common diseases in a minor way various septic skin conditions took a high place. This we thought to be due to dietary deficiency. In view of the fact that a very similar high proportion of "I.A.T." is found in German P.o.W.s in this country, however, on a vastly different and well-balanced diet, one is led to think that a lack of immunity to local micro-organisms may be a more potent factor in the aetiology.—I am, etc.,

Aveley, Essex. John Kennedy.

Medical Views of Nurses' Training

Sir,—The Liverpool Hospitals Staffs Association consists of the honorary medical staffs of the nine Liverpool teaching hospitals. The following resolution was passed at a general meeting this week, and it is hoped that you will have space to publish it:

> "This Association express their deep concern with the increasing trend towards demanding of nurses too detailed a theoretical and scientific knowledge, to the discouragement of practical craftsmanship. The members of this Association believe that the qualifying standard for registration should be based very largely on practical experience and vocational training. For all higher and specialized forms of nursing, a further and more scientific type of training should be demanded."

—I am, etc.,

Liverpool. A. Kirk Wilson.

Women in Labour

Sir,—Reading Dr. Kathleen Vaughan's letter (Sept. 29, p. 443) recalled to my mind, first, that some years ago the same observations on the maternal squatting position were reported in one of the medical journals, but whether by Dr. Vaughan or not I cannot now remember. Secondly, six years ago I was urgently summoned to a confinement case—a young married woman who lived alone with her crippled mother. When I entered the bedroom I was surprised to find the bed empty, but on the far side I discerned the patient naively squatting on the chamber-pot in which she had given birth to a premature baby which weighed 3 lb. and is a healthy girl to-day. The only point about all this is that if it proves anything it is that this rather simple girl, ignorant of the usual procedure and left entirely to her own instincts and resources, had adopted what is most probably the natural position for labour.

Finally my contribution, as a general practitioner of 25 years' standing (though not all spent in general practice), to those correspondents on domiciliary midwifery is, let me attend all my cases in hospital, whether they be normal or abnormal, rich or poor.—I am, etc.,

Keighley. Wright Lambert.

Sir,—In the *Journal* of June 30 (p. 925) there appears a letter from a Mr. Eric Coldrey which interested me greatly. For many years I have practised the induction of labour for the purpose of limiting the size of the child to the easy capacity of the mother. I have delivered several post-Caesarean cases without any difficulty, and a considerable number of cases with very small pelves where I had to induce at 5½ to 6 lb.

I have preached this "small baby" idea at every opportunity but have made few converts because, like Mr. Coldrey, all are afraid of using rupture of the membranes as part of the induction (and the most essential part). Rupture of the membranes is a certain and safe method of induction providing it is not done blindly. It should be done at the level of the internal os with the tip of the index finger in contact with the end of the instrument used, whether a curved long artery forceps or one of the specially made puncturing catheters. I have used this method of induction in many hundreds of cases and am convinced of its absolute safety. I use it in conjunction with the medicinal treatment mentioned by Mr. Coldrey.—I am, etc.,

M. Schwartz,
B.W.I. Chief Medical Officer, Trinidad Leaseholds Ltd.

Telling the Patient

Sir,—During a recent short visit to England I have had forcibly brought to my notice a matter which has often troubled me in the past because of its fundamental importance in the treatment of ill people. In my capacity as medical specialist I have been attached to a military hospital with a large out-patient department for a period of six weeks while awaiting my ship. What impressed me most while I worked in the out-patient department was not the obviously careful and detailed examinations and investigations lavished upon the patients by their unit doctor and by specialists (for most of the men had seen several specialists), but the fact that in only a small proportion did the patients possess accurate information regarding their particular illnesses. Most of them were quite uninformed about diagnosis, prognosis, and treatment, and when questioned would quickly show that they had their own ideas—quite inaccurate—based upon a few words picked up from their doctor or orderly.

As an example of this I can remember a man of 20 who had weakness and wasting of muscles of one leg due to anterior poliomyelitis contracted at the age of 12 years. He had an unsuitable job in the Army involving excessive use of the leg, and, in consequence, he had some discomfort. He was first seen by a medical specialist, who correctly made the diagnosis of "old poliomyelitis" and referred him to an orthopaedic surgeon. He later decided that no orthopaedic treatment was necessary. The patient, misinterpreting what he had overheard, decided that his condition had gone beyond the stage when treatment was worth while and, naturally enough, became extremely worried, both as regards his future in the Army and his future as a wage-earner. A five-minute interview in which the exact state of affairs was explained to him in simple language completely relieved his anxiety.

I encountered exactly the same difficulty in an E.M.S. hospital during the first three years of the war. The young medical men working there were keen to reach an accurate diagnosis and to apply the correct treatment as soon as possible. Many of them, however, failed to appreciate the importance of the few moments necessary to explain to the patient the points about his illness which were important to him as a wage-earner and as one of a family. As a result of this, patients were apt to acquire quite a wrong idea of their illness from the mutterings and noddings of a group of doctors at the bedside. Surely it is a complete waste of experience, talent, and modern science if, through neglect of a simple basic principle, we are left with a correctly diagnosed and correctly treated but completely bewildered and apprehensive patient. Surely we can train ourselves to speak to patients in a language they understand and to make sure that they do understand what we are trying to tell them.

I know, Sir, that this topic is hackneyed, but I cannot believe it to have been over-emphasized yet. I hope you will find room in your columns for this letter.—I am, etc.,

J. C. HOGARTH,
Major, R.A.M.C.

Doctors and the Social Trend

SIR,—When reading the *Journal* of Sept. 1 my attention was drawn to a letter from Dr. Norman P. Henderson (p. 302). Among other things Dr. Henderson refers to the Soviet full-time medical service by stating: ". . . in the event of the full-time service failing (as it has to a large measure in Russia) . . ." Far from having failed, the full-time medical service in the Soviet Union operates extremely successfully. This has been proved in peace as well as in wartime. It was, therefore, with considerable surprise that I noted Dr. Henderson's statement, and I should be interested to know what actually was in Dr. Henderson's mind when making this allegation.—I am, etc.,

London, W.2. S. SARKISOV.

SIR,—It might seem churlish to criticize the work of our Russion ally, but Drs. Culbert (Sept. 15, p. 369) and Fieldman (Sept. 22, p. 406) press the issue and make it necessary that criticism and the facts should be offered.

In *Health Protection in the U.S.S.R.*, by N. A. Semashko, the publisher's note aptly records the "great numbers of books on the Soviet Union. Indeed the lack of really precise and definite information has been noticeable as the plethora of impressions." Dr. Fieldman's references are typical additions, exemplified in Prof. Adrian's article by an enthusiastic description of how he was "dazzled as before by stately entertainment," returning laden with "gifts of reprints and books," etc. Terminating on a more sober note he finds "in physiology there have been few outstanding advances in recent years, in the U.S.S.R. or anywhere else." It seems rather trifling for Dr. Fieldman to quote "impressions" on physiology as examples of efficiency, or otherwise, of Russian State medicine. Prof. Sorsby's contribution admits that "our knowledge of Soviet medicine is at all times inadequate and at times grossly misinformed." Dr. Fieldman's third reference, *Socialised Medicine in the Soviet Union* (1937), some eight years out of date, was originally compiled for followers of the extreme left, but in parts to-day conflicts with the more moderate and modern author of *Red Surgeon* (1944), by G. Borodin. It is evident from this book that the Russian medical services did fail at times owing to the fault of organization and pathetic shortage of medical equipment, drugs, and personnel, and yet over twenty-seven years had been spent in preparation. The author laments the shortage of surgeons, and relates how physicians had to turn surgeons, with sometimes disastrous consequences. Corroboration of these facts is found in *American Review of Soviet Medicine* for Feb., 1945. Yet Dr Culbert feels that the Russian accomplishments "would hardly have been possible with any other form of organization."

In the Czarist Empire in 1913 there were fewer than 20,000 doctors, and as the authors of *Red Medicine* (1934) observe, "the people . . . outside the large cities were almost destitute of medical aid." To-day about 150,000 doctors practise, but still the number is inadequate. Nevertheless with this seven-fold increase some improvement of the health of the nation was inevitable—as indeed has come about—irrespective whether State-controlled or no control at all. When, however, we consider vital statistics of disease in Russia compared with other countries, including our own, for equal units of population the differences are striking and the backwardness of Russia apparent.

As for research, what has come out of vast organizations like the Institute of Experimental Medicine, Moscow, comparable to recent discoveries in other European countries, such as the sulphonamides, penicillin, or sex hormones? In *Science and Planned State*, by John R. Baker (1945), is the astonishing revelation that sex hormones were banned from study under the first five-year plan.

And Semashko himself states that "the most popular doctors and professors are able to earn extra money from private medical practice in addition to their salary from the State." It does seem extraordinary that such is permitted and that the Soviet service finds this additional help from private practice necessary.

Owing to limitation of space I am unable to respond to Dr. Bailey.—I am, etc.,

London, W.1. NORMAN P. HENDERSON.

⁂ We cannot continue this correspondence.—ED., *B.M.J.*

Tea-making and Tuberculous Milk

SIR,—An article by Hiscox (1944) has drawn attention to the bacteriological aspects of high-temperature short-time (H.T.S.T.) pasteurization of milk. In discussing the spread of bovine tuberculosis by milk, Cutbill and Lynn (1944) drew attention to the lack of evidence of widespread habitual raw-milk drinking in the area covered by their investigation, but confirmed the almost universal practice of taking milk in tea or similar beverages.

A search through the literature failed to reveal any information about the effect of using tuberculous milk in hot beverages. The classical work of North and Park (1927) gives the thermal death-point of tubercle bacilli, and it was therefore only necessary to determine the temperatures to which milk would be exposed when used as an ingredient of tea. Surprisingly high temperatures of the order of 155° F. are retained by tea over periods up to 20 minutes after infusion—high enough to kill tubercle bacilli in 30 seconds. Where such conditions prevail infected milk would be rendered sterile. To confirm the correctness of such deductions we prepared tea in a normal household manner; five minutes later the hot infusion was poured into a cup containing heavily infected tuberculous milk. After the elapse of 30 seconds a portion was withdrawn from the cup, cooled rapidly, and centrifuged, and a guinea-pig was inoculated with a portion of the untreated deposit suspended in saline. The remainder of the deposit was stained by Ziehl-Neelsen's method and also cultured on Loewenstein's media. Ten minutes after the initial infusion a further cup of tea was poured out, when the temperature had dropped somewhat lower, and treated exactly as the first cup. The complete experiment was repeated a few weeks later, using the same technique but different utensils and a milk inoculated with a known virulent bovine strain. The guinea-pigs and cultures were negative in all instances. The deposits from the tea-cup showed large numbers of tubercle bacilli which were apparently dead. Both raw milks produced severe general tuberculosis in guinea-pigs, and typical dysgonic strains were isolated on culture.

The conditions of tea-making and consequent temperature gradients vary so widely in practice that it would be unwise to draw too sweeping deductions from our findings. Reliance on the sterilization of milk by hot tea or other beverage without precisely defining the conditions would be folly. This protective factor does enter into epidemiological investigations of the spread of bovine tuberculosis and appears to be of a high order.—I am, etc.,

Permission to Practise for Enemy Aliens

SIR,—I would ask the controversialists engaged in discussing the many current problems of undeniable importance to the medical profession to pause for a moment and give thought to a matter involving our humane outlook and our sense of fairness. There are in our midst a number of so-called enemy alien doctors, who, having suffered every conceivable indignity, including, in some cases, imprisonment in the notorious Dachau camp, and what seemed to many of them a greater indignity, internment in one of our camps, were permitted by us because of our dire need to attend our sick during the later years of the war, performing their duties conscientiously and well. Permission for them to practise here ceases in February unless other arrangements are made.

I am informed that we are awaiting the decision of the Government on this question, but I cannot help feeling that in actual fact the Government is waiting for an expression of medical opinion, and I write to suggest that those enemy-alien doctors who have served us to the best of their ability during the war be granted permission to continue in practice here, for it cannot be demanded or expected that many of them would be ready to return to the land which had treated them so outrageously and caused them many years of unhappiness, such as few have to bear.—I am, etc.,

London, W.8. HAROLD H. SANGUINETTI.

Obituary

T. WILSON PARRY, M.A., M.D., F.S.A.

We regret to announce the death of Dr. T. Wilson Parry, for many years a greatly respected practitioner in North London whose antiquarian researches in a special field made him well known to archaeological circles.

Thomas Wilson Parry was born at Sydenham, Kent, on July 23, 1866, son of Joseph Chatwin Parry. From Amersham Hall School he entered St. John's College, Cambridge, in 1884, took the B.A. with honours in the Natural Sciences Tripos of 1887, and the M.A. in 1891 while doing his clinical course at St. George's Hospital. He qualified M.R.C.S., L.R.C.P. in 1892, and graduated M.B., B.Ch. in 1894, and M.D. in 1905 with a thesis on Ménière's disease, a subject to which he returned two years later in a paper read before the Tottenham Branch of the B.M.A. While in practice at Crouch End Hill Wilson Parry held a commission as surgeon-captain in the 3rd City of London Volunteer Regiment for five years, and in the war of 1914–18 he served as M.O. to the 5th Battalion of the Middlesex Regiment; he was also for many years a lecturer for the St. John Ambulance Association, which made him an honorary Life Member, and examiner for the Red Cross Society. He invented two appliances—a seton knife-needle, and a curved sublingual clinical thermometer. From 1916 onwards he published a series of papers on trephining among prehistoric and primitive peoples. The first of these was on the motives for its practice and the methods of procedure, read before the British Archaeological Association; the second, read before the History of Medicine Section of the Royal Society of Medicine, was on the prehistoric trephined skulls of Great Britain, with detailed description of the operation probably performed in each case; the third was an examination of the collected evidence of trephination of the human skull in Great Britain in prehistoric times, read at the third International Congress of the History of Medicine; and the fourth was on trephination of the living human skull, read to the Lister Society of King's College Hospital. Wilson Parry joined the B.M.A. in 1894, and twice held office in the History of Medicine Section at Annual Meetings, was a Fellow of the Society of Antiquaries and the Geological Society, and a past-president of the North London Medico-Chirurgical Society.

Sir WALTER LANGDON-BROWN writes:

Although Dr. Wilson Parry had retired from practice for a number of years he will still be remembered by many with admiration and affection. His father, a bank manager, played an important part in the defence of Lucknow. Parry was educated at Amersham Hall, then a well-known nonconformist school, which numbered amongst its distinguished alumni such men as Augustine Birrell, Buckston Browne, and Cozens-Hardy. Thence he proceeded to St. John's College, Cambridge, and to St. George's Hospital, where he held several resident appointments. He started practice at Youlgreave, Derbyshire, in 1894, but eight years later moved to Crouch End, where the rest of his professional life was spent. Sympathetic, gentle, and courteous, he endeared himself to his patients, and to these qualities was added a fine clinical acumen which made him representative of the best traditions of the general practitioner. Devoted as he was to practice, it by no means exhausted his activities; his status as an anthropologist secured his election as a Fellow of the Society of Antiquaries, and he became the leading authority on prehistoric trephining. His poetic gifts were both graceful and learned, as is shown in his sonnet sequence *Great Names* and in his fairy poems, which reveal his tender insight into the minds of children. Sincerely religious, one felt his essential goodness; he loved whatsoever things are lovely and of good report. In 1937 he became seriously incapacitated by ill-health, against which he struggled gallantly, but was able to continue with some of his literary work. It was a great joy to him that in 1942 he was well enough to be able to revisit his beloved university. But the improvement was only temporary, and the end came peacefully on Sept. 21.

In 1894 he married Miss Sophie Cole, by whom he had two sons, both now in the medical profession, and one daughter who, to their great grief, died as the result of a bathing accident at the age of 19. The sympathy of all who remember him will go out to Mrs. Wilson Parry, whose devoted care and companionship sustained him all his days.

Sir ERNEST GRAHAM-LITTLE writes:

Dr. Wilson Parry and I entered the wards of St. George's Hospital at the same time and clerked for the same physician, and a close friendship between us thus ensued which was unbroken up to his death. He was gifted in many directions as well as in medicine. He had a happy talent for verse, especially in the form of the sonnet, and was accustomed for many years to send to his friends—and I was a constant recipient—Christmas greetings conveyed in a very delightful sonnet. He had made a serious study of the history of trepanning, and had established the ancient existence of its practice by examining prehistoric skulls. He was a staunch upholder of the best ethical traditions of the profession, he enjoyed a large practice, and was much loved by a wide circle of patients. He was especially fortunate in his family life, and was greatly gratified that his two sons elected to adopt medicine as their profession.

RICHARD TRAVERS SMITH, M.D., F.R.C.P.I.

We regret to record the death on Sept. 28 of Dr. Travers Smith, late Professor of Materia Medica and Therapeutics in the University of Dublin, whose passing will be mourned by a large circle of friends, both within and outside the medical profession.

Richard Travers Smith was born on May 26, 1872, the second son of John Chaloner Smith, of Bray, Co. Dublin. He was educated at Strangeways School and later at Trinity College, Dublin, where he graduated M.B., B.Ch. in 1894, proceeding to the M.D. in 1896. Almost immediately after graduation he went to Vienna to pursue a course of postgraduate study. This was unexpectedly cut short owing to the death of his father, and he was obliged to return after a few months to Dublin and to start practice. He worked extremely hard as a general practitioner, taking many pupils whom he coached for their medical examinations, thus laying the foundation of his later work as a teacher, for which he enjoyed a well-deserved reputation. It was not long before his aim to devote himself to internal medicine was realized and he took his place as a physician on the staff of the Richmond, Whitworth, and Hardwicke Hospitals in Dublin. He became a Fellow of the Royal College of Physicians of Ireland in 1899, and was eventually a Censor of the College, and Professor of Materia Medica and Therapeutics in the University. He came over to this country in 1915 for the war, and was appointed to the Military Hospital in Colchester in charge of a medical division with the rank of major in the R.A.M.C. After demobilization he was appointed honorary physician to the Miller General Hospital for South-East London and consulting physician to the West Middlesex Hospital. After his retirement from the active staff of these institutions, on reaching the age limit, he was made honorary psychotherapist to the West End Hospital for Nervous Diseases, and continued to hold this office until the time of his death.

A correspondent writes: Those of his colleagues who knew him well and were most closely associated with his professional work will remember Travers Smith (Dick Smith, as he was affectionately known to his intimate friends) as a great gentleman and a fine physician of the old school. Although in the latter part of his career he devoted himself mostly to the practice of psychological medicine, in which he had always taken a special interest, he never let go his hold on general medicine, and the influence of his earlier training and work as a general physician was always apparent in his outlook as a practitioner. He never forgot the patient in his pursuit of the problem of disease, and the pleasure of consultation with him was enhanced by the broad humanitarianism and the wide general culture which he brought to bear upon the purely technical aspects of his work, and which coloured his whole outlook not only on medicine but also on life in general. It is not without significance that he was one of the original members of the Association of Physicians of Great Britain and Ireland founded by Sir William Osler in 1908, election to this august body being, especially in those early days, a hall-mark of fellowship with the intellectual aristocracy of the profession.

By his colleagues in London on the various hospitals he was indeed beloved, not only for his medical experience and judgment, but especially for his good humour and for the quick and ready wit which was an integral part of his attractive personality. He was a welcome guest at medical dinners, to the enjoyment of which he added so much by his native skill as a raconteur. In private life he was a charming host, full of wide interests and with great knowledge of the arts and of the humaner letters. During the last few years of his life his health began to show signs of the wear and tear of years, accentuated by the strains and stresses of the recent war, but neither these nor the added tax imposed by a recent attack of pneumonia with other complications diminished in any wise his interest in all the finer joys of this world or impaired his gentle humour and rare companionship, which continued up to the very end. Death came to him swiftly and silently, as he would have wished. Those whom he has left, while mourning his loss, yet rejoice in his memory and are grateful for his contribution to their lives.

WILLIAM MARCUS KILLEN, M.D., M.Ch.

The death of Dr. W. M. Killen on Sept. 1 breaks almost the last surviving link between the present clinical teachers of the Belfast Medical School and those of the last century.

William Marcus Killen was born in 1863, a son of the manse, his father being the Very Rev. T. Y. Killen, D.D., who was a leading divine at that time in the Irish Presbyterian Church. Educated at the Royal Academical Institution, Belfast, he entered Queen's College, Belfast, and graduated B.A. in 1884 with first-class honours and exhibition, and in the same year was awarded the senior scholarship in natural history. Three years later he obtained the M.D., M.Ch., M.A.O. degrees in the Royal University of Ireland. After a period of study at the London Hospital, in Dublin, and in Vienna, he was appointed in 1892 assistant surgeon to the Benn Ulster Eye, Ear and Throat Hospital, Belfast. It was in this hospital that the late Dr. D. H. McKeown introduced the practice of early operation on immature cataracts and the use of a magnet for the removal of metallic foreign bodies from the eye. On the death of Dr. McKeown in 1904 Dr. Killen became senior surgeon—a post he held until his resignation in 1934, having served that institution for a period of 42 years—and during the first world war carried on the work of the hospital practically single-handed.

A colleague writes:

> Quiet and unassuming by nature, and happiest in his clinical and teaching work, Dr. Killen did not seek high honours, but his colleagues in Belfast persuaded him to accept the chairmanship of the Belfast Division of the B.M.A. in 1912, and his outstanding work in his special subject led to his election to the presidency of the Irish Ophthalmological Society and vice-presidency of the Section of Ophthalmology of the B.M.A.
>
> Dr. Killen was a great conversationalist. One of his greatest pleasures was to welcome any of his large circle of friends to his hospitable fireside, where, in the happy interchange of talk, time was forgotten. Descended from generations of clergy, he retained throughout his life an intense interest in theological problems, and sooner or later the conversation turned to such subjects as the rival doctrines of free will and predestination or the reconciliation of religious faith with scientific principles, and other kindred questions. Although brought up in a strict Calvinistic atmosphere (where even the singing of hymns and the introduction of instrumental music into the Presbyterian church service was viewed with dislike and suspicion) Dr. Killen was the most liberal-minded of men: he always studied both sides of a question and respected the other man's outlook; like Montaigne he believed that often "to know all was to forgive all." He was the most generous of men: no deserving charity was refused, private patients in difficult circumstances were treated free, and hospital patients sometimes became pensioners from his purse.
>
> William Marcus Killen, although reaching a patriarchal age, died young, with his intellect clear and his mind elastic and receptive, and still retaining the affectionate regard of former patients, students, and colleagues.

Universities and Colleges

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

The sixteenth annual report of the Royal College of Obstetricians and Gynaecologists has been issued from its headquarters, 58, Queen Anne Street, London, W. During the year Honorary Fellowship was conferred on Dr. Hastings Tweedie, of Dublin, for his outstanding services as a teacher and practitioner of obstetrics and gynaecology, and on Sir Joseph Barcroft for his work on the physiology of the foetus. For the first time in the history of the College the Council decided to elect to the Fellowship a limited number of practitioners who are not obstetricians and gynaecologists but who have, by their scientific and other work, aided obstetrical and gynaecological practice; and Dr. Leonard Colebrook, bacteriologist, and Prof. Leonard Parsons, paediatrician, were admitted to the Fellowship. At the annual general meeting on May 26, 1945, the President, Mr. Eardley Holland, gave an account of the work that the College is doing and mentioned the problems still under consideration and awaiting solution. The two events of 1944 that concerned the College most were the publication of the White Paper on a National Health Service, and a little later the publication of its own report on a National Maternity Service. The White Paper in so far as it dealt with obstetrics and gynaecology he found frankly disappointing. It was only too evident that the machinery proposed to assist women through the reproductive period showed no improvement on the existing services.

POSTGRADUATE COURSE IN RHEUMATISM

The Empire Rheumatism Council (B.M.A. House (North), Tavistock Square, W.C.) has arranged a postgraduate course to be held from Oct. 31 to Nov. 11, both dates inclusive. The items marked with an asterisk will be held in conjunction with the annual meeting of the Heberden Society at the hospitals indicated. All the other lectures will be given in the board room of the British Red Cross Society's Clinic for Rheumatism (Peto Place, N.W.), by kind permission of the society. The programme is as follows:

Oct. 31, 4 p.m., Mr. N. Capener, "Body Mechanics—Posture and Its Control"; 5 p.m., Dr. A. Wesson, "Abnormalities of Posture and Chronic Strain."

Nov. 1, 12 noon, Prof. G. W. Pickering, "The Skin and Its Reactions"; 4 p.m., Prof. Pickering, "The Nervous System—Referred and Segmental Pain"; 5 p.m., Mr. D. V. Davies, "The Anatomy and Physiology of Joints."

Nov. 2, 12 noon, Dr. G. Kersley, "Recent Trends in Aetiological Concepts"; 3 p.m., Prof. Bruce Perry, "Rheumatic Fever"; *5 p.m., at Royal Free Hospital, Lecture-demonstration by Dr. C. B. Heald, "Recent Advances in Physical Methods in Relation to Rheumatism."

*Nov. 3, 10 a.m., at Middlesex Hospital, Lecture-demonstration by Prof. B. Windeyer, "Deep X-ray Therapy of Spondylitis"; *12 noon, at Middlesex Hospital, Brig. F. D. Howitt, "Social Medicine in Relation to the Rheumatic Diseases."

Nov. 4, 11 a.m., Dr. J. W. T. Patterson, "The Factor of Infection in Rheumatism and Arthritis"; 12 noon, Sir Adolphe Abrahams, "Rheumatic Symptoms in General Medicine."

Nov 5, 12 noon, Dr. C. W. Buckley, "Spondylitis"; 4 p.m., Dr. W. Tegner, "Rheumatoid Arthritis"; 5 p.m., Dr. J. Barnes Burt, "Gout."

Nov. 6, 12 noon, Lord Horder, "The Clinical Approach to Rheumatic Disease"; 4 p.m., Dr. Ernest Fletcher, "Osteo-arthritis"; 5 p.m., Dr. W. S. C. Copeman, "Fibrositis."

Nov. 7, 12 noon, Mr. A. G. Timbrell Fisher, "The Painful Back"; 4 p.m., Dr. Hugh Burt, "The Painful Knee"; 5 p.m., Wing Cmdr. N. S. Alcock, "Sciatica"; 6 p.m., Dr. B. E. Schlesinger, "Still's Disease."

Nov. 8, 12 noon, Dr. S. J. Reynolds, "The Radiology of Normal Bones and Joints"; 4 p.m., Dr. Campbell Golding, "The Radiology of Rheumatic Disease"; 5 p.m., Dr. P. Ellman, "Psychological and Occupational Factors in Chronic Rheumatism."

Nov. 9, 12 noon, Dr. J. W. Shackle, "Methods of Investigation and Their Significance"; 4 p.m., Dr. F. S. Cooksey, "Physical Medicine, Remedial Exercises, and Physiological Rest"; 5 p.m., Dr. F. Bach, "Specialized Methods of Medical Treatment in Rheumatism."

Nov. 10, 12 noon, Dr. Kenneth Stone, "Classification and Pathology"; 4 p.m., Dr. J. Bastow, "Orthopaedic Aspects of Rheumatoid Arthritis"; 5 p.m., Mr. A. M. A. Moore, "The Surgery of Arthritic Joints."

Nov. 11, 11 a.m., Dr. M. B. Ray, "Environment, Housing, and Dietetic Factors in Relation to Rheumatic Disease"; 12 noon, Dr. L. G. C. Pugh, "Precipitating Factors—Climate, Environment, etc."

No. 38

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Sept. 22.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1945					1944 (Corresponding Week)

Annual death rate (per 1,000 persons living)			12·2	12·5	§			14·1	12·1	§
Live births	6,463	814	828	369	265	6,283	414	926	386	283
Annual rate per 1,000 persons living ..				23·8	§			18·8	25·0	§
Stillbirths	189	23	35			191	12	37		
Rate per 1,000 total births (including stillborn)			41					38		

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to movements of population, birth and death rates for Northern Ireland are still not available.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* measles returns were 154 lower than last week, whooping-cough 66 lower, and dysentery 22 lower; no disease showed any appreciable increase.

The figure for measles was the smallest recorded since notification began. Scarlet fever was down by 20 cases, but there was a small rise in London, Middlesex, and Essex of 53 notifications for the combined area. The largest variations in the local trends of diphtheria were increases in Lancashire 18, Durham 15, and Yorks West Riding 12. Diphtheria incidence has steadily gone up in Lancashire during recent weeks. An irregular rise in acute poliomyelitis started at the beginning of July, and from a fairly constant level of 6 cases weekly it has risen to 45—the largest weekly total for four years.

The biggest local outbreaks of dysentery during the week were Hertfordshire, Ware R.D. 21, and Suffolk, Lowestoft M.B. 37. The other large returns were London 41, Lancashire 39, Surrey 22, Essex 15, Yorks West Riding 12.

In *Scotland* dysentery notifications went up by 30, but those for scarlet fever dropped by 22, for whooping-cough by 16, and for diphtheria by 13. The rise in dysentery was mainly in the western area, the largest returns being those of the cities of Glasgow 55, Edinburgh 17, Falkirk 13.

In *Eire* 15 fewer cases of diphtheria were notified. Whooping-cough notifications increased by 21, due to an outbreak in Dublin C.B. The incidence of diarrhoea and enteritis among infants under 2 years of age fell by 46, but remained at the high level of 101 cases, of which 84 were reported in Dublin C.B.

Week Ending September 29

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,509, whooping-cough 920, diphtheria 486, measles 406, acute pneumonia 302, cerebrospinal fever 17, acute poliomyelitis 40, dysentery 264, paratyphoid 11, typhoid 15.

Medical News

Fourteen-day refresher courses (22 sessions) for medical officers returning from H.M. Forces will begin at Addenbrooke's Hospital, Cambridge, on Monday, Nov. 5, and at Southend-on-Sea General Hospital on Monday, Dec. 3. Applications for further information and admission to these courses should be made to Dr. Firth, Trinity Hall, Cambridge.

The United Kingdom delegation to the United Nations Food and Agriculture Conference which is to open at Quebec on Oct. 16 in continuation of the work at Hot Springs, Virginia, in 1943, will include Sir Jack Drummond, F.R.S., scientific adviser to the Ministry of Food, and Dr. B. S. Platt, director of the human nutritional research unit of the Medical Research Council. The main task before the conference is to set up a permanent organization in the field of food and agriculture.

Dr. C. M. Wenyon, F.R.S., will give his presidential address on "Tropical Medicine in War and Peace" to the Royal Society of Tropical Medicine and Hygiene at Manson House, 26, Portland Place, W., on Thursday, Oct. 18, at 8 p.m. Refreshments will be served in the library from 9 p.m.

The Institution of Chemical Engineers, the Institute of Physics, and the Chemical Engineering Group of the Society of Chemical Industry announce that the one-day joint conference on "Instruments for the Automatic Controlling and Recording of Chemical and Others Processes," which was postponed in September, 1944, will take place at the Royal Institution, Albemarle Street, London, W., on Friday, Oct. 19. The purpose of the conference is to promote the interchange of knowledge and experience between those using automatic controllers and recorders in different fields and to encourage collaboration. The conference will be open to all interested, without charge.

The inaugural meeting of the Bristol Council for Rehabilitation (sponsored by the Bristol and District Divisional Hospitals Council) was held in the Council House on Oct. 4, when Mr. Harold Balme, F.R.C.S., medical officer in charge of rehabilitation, Ministry of Health, gave an address.

The Lord President of the Council has appointed Prof. R. P. Linstead, D.Sc., F.R.S., to be director of the chemical research laboratory in the Department of Scientific and Industrial Research. He was formerly Firth professor of chemistry in the University of Sheffield and in 1939 was elected to the chair of chemistry in Harvard University, U.S.A. During the war he returned to Great Britain and has rendered valuable service in relation to the application of science to war problems.

Mr. V. Zachary Cope, F.R.C.S., president of the Board of Registration of Medical Auxiliaries, will give an address on "The Place of Physiotherapy in a Co-ordinated Health Service" on Saturday, Oct. 20, at 3 o'clock, at the Royal Institute of Public Health and Hygiene, 28, Portland Place, W. The Minister of Health, the Rt. Hon. Aneurin Bevan, M.P., will take the chair. All physiotherapists are invited, but admission will be by ticket only, which can be obtained on application to the hon. secretary, Society of Physiotherapists, 24, South Molton Street, London, W.1. Student physiotherapists will also be welcome.

The Institute of Laryngology and Otology (330–332, Gray's Inn Road, London, W.C.), in association with the Royal National Throat, Nose and Ear Hospital, has arranged a five-weeks course in laryngology, rhinology, and otology for senior postgraduate students, especially those taking Part II of the D.L.O. examination, from Oct. 29 to Nov. 30. The fee for the course is £15 15s., and the full syllabus may be obtained from the secretary of the institute. Demonstrations and discussions of clinical cases will be held on Fridays at 4 p.m. from Dec. 14, 1945, to April 19, 1946, and are open to all medical practitioners without fee. Clinical-assistantships and out-patient assistantships are available at both the Gray's Inn Road and the Golden Square Hospitals.

A Department of Industrial Ophthalmology has been set up at the Royal Eye Hospital, London, where the problems being investigated include: (1) Prevention of eye injuries (the type and the efficiency of preventive appliances). (2) Welders' conjunctivitis (arc eye). (3) Lens opacities in furnace workers, welders, etc. (4) Rehabilitation of the worker with one eye. (5) Eye strain of workers engaged on fine close work. (6) Eye strain due to deficient illumination during work. (7) Keratitis, conjunctivitis, amblyopia, due to the use of industrial solvents. (8) Vision and the selection of staff in industry (visual standards in industry). Industrial medical officers, factory welfare officers, safety managers, and others interested are invited to refer their problems in industrial ophthalmology to Mr. J. Minton, F.R.C.S., who has been appointed ophthalmologist to the department, at the Royal Eye Hospital, St. George's Circus, London, S.E.1.

The 37th annual meeting of the Medical Benevolent Society for the North and East Ridings of the County of York (including the City of York) was held at York on Sept. 25, by kind permission in the library of the York Medical Society, Stonegate. The report of the honorary secretary showed a most satisfactory state of affairs, the membership again having reached a new high level. Two applications for assistance were considered, and in both cases grants were made. The treasurer's audited accounts indicated that the finances of the Society were in a healthy state, and that funds were available for further investment. Great regret was expressed at the impending retirement of the honorary treasurer, Dr. Matheson Mackay, whose association with the society dates back to 1909, and who held the office of president in 1929 and 1930. Applications for membership should be addressed to Dr. W. W. A. Kelly at 92, Micklegate, York.

The Health Division U.N.R.R.A., London, invites the attention of members of the profession, below 50 years of age, who have been practising in a specialty of medicine or surgery, to the advertisement in the *Journal* of Sept. 29 for specialists for service in China for a period of about a year. This would appear to be a unique opportunity for them, not only for participating in the professional rehabilitation of our great Ally, but for obtaining fresh experience with a possibility of openings for practise in that country for those who care to remain when U.N.R.R.A. has withdrawn.

The Vice-Chancellor of the University of Leeds, Mr. B. Mouat Jones, speaking at the medical degree ceremony on Sept. 22, said that he had been notified of a considerable grant for the development of facilities for medical teaching in the university so that it would be possible to make a start on post-war schemes. With regard to the intake of new medical students, the Vice-Chancellor said that the need for more doctors had evidently impressed itself on the public. The Leeds Medical School had had 999 applications for admission in the present session and there were 75 vacancies. Already the applications for the following session were well over the available places. When building permits were eventually obtained to enlarge the accommodation to deal with an annual intake of 100—which was the maximum thought desirable and was the figure recommended by the Goodenough Committee—it would still be quite impossible to satisfy the demand for admission if it kept at its present rate. It was well that this should be generally known so that parents might contemplate alternative careers for their sons and daughters.

Mr. A. J. Bennett, previously assistant secretary, has been appointed secretary and chief executive officer of the Central Midwives Board for England and Wales from Oct. 1, in succession to Mr. Leslie Farrer-Brown.

The following members of the medical profession have been released from internment in Japanese hands: Dr. Oscar Elliott Fisher and Dr. John Groscort Reed.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Aitiology Westcent, London.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London.*

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Westcent, London.*

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Pregnancy after Thigh Amputation

Q.—*A girl aged 17 had a high thigh amputation; she used crutches for two years and was then fitted with an artificial leg. She is now 22, married, and pregnant. She wishes to know whether she should continue to wear her artificial leg during her pregnancy. She is quite prepared to go back to crutches, on which she is very agile. Is there any likelihood of her two years on crutches when younger having caused any great deformation of her pelvis which might give trouble at labour?*

A.—Unless she develops any trouble (e.g., circulatory) in the stump there is no reason why the patient should not continue to wear the artificial leg during pregnancy, and it would be preferable to crutches.

By the age of 17 years the development of the pelvis is well advanced, so unequal weight-bearing at that age is much less likely to have any effect on its shape than it would have in the earlier and more formative years. At most there might be slight atrophy of the pelvic bones on the side of the amputation, or some inward displacement of the wall of the pelvis on the sound side. Even so the oblique deformity, if any, will be of a minor degree and most unlikely to cause mechanical difficulty in labour. However, it would perhaps be wise to have the pelvic shape and measurements determined radiologically, and especially if there is any doubt about the fit of the head into the brim during the later weeks of pregnancy.

Purpura after Sedormid

Q.—*With reference to the question on purpura in the* JOURNAL *of Aug. 25 (p. 271), is the purpuric reaction after sedormid likely only after prolonged sedormid treatment, or does it follow immediately after a few tablets? Which radical in the formula causes purpura?*

A.—The amount of sedormid necessary to produce purpura varies greatly. Purpura has occurred after a single tablet. In other instances the patient has taken sedormid regularly for two or three years before sensitization has developed. Between these extremes every variation in time has been seen. Details of 41 cases of sedormid purpura have been summarized by Falconer and Schumacher (*Arch. intern. Med.*, 1940, **65**, 122). There are safer alternatives which practitioners can use.

Sedormid is allyl-isopropyl-acetyl carbamide, and it belongs to the group of carbamides, or acylic ureides, in which one H of the urea ($H_2N.CO.NH_2$) is replaced by an acid radical. Other members of this group are carbromal and bromural, but they are not known to affect the blood-forming organs. The acid radical in sedormid does not look very dangerous, and presumably the complete molecule is necessary for sensitization. This group of compounds is fairly closely related chemically to thiourea and thiouracil, which have an unpleasant tendency to produce agranulocytosis.

Low Blood Pressure

Q.—*I would be glad of advice on investigation and treatment of low blood pressure in general. I am finding many patients with a systolic pressure of as little as 110 or even 95, all complaining of lassitude and lack of "staying power." Low blood pressure seriously handicaps these patients, and I would appreciate suggestions.*

A.—The range of the normal blood pressure in health may well extend down to 100 or even 95 mm. Hg. It is not so uncommon to meet healthy young people who have pressures of this level. They are often of slight asthenic build and have slow pulses. Above the age of 40 such pressures are usually abnormal. The symptoms commonly associated with hypotension are lassitude, fatigue, giddiness, weakness, faintness, and a poor capacity for exertion. Patients with such symptoms not uncommonly do not have an abnormally low pressure. So the symptoms and the pressure do not necessarily run parallel.

To gauge the significance of a low reading in any individual with symptoms one must know what his pressure is in normal health. The blood pressure depends upon several factors. It will fall in some cases of severe myocardial damage, but here the cause is obvious; an infarct is the commonest cause. At the periphery the tone of the arterioles is the most important influence. This depends on the activity of the vasomotor centre and upon the state of the arterioles themselves. This last is influenced by the secretions of the adrenals and the pituitary body, and probably also of the kidneys. Changes in the blood volume hardly come in here, and one need not discuss shock. Anaemia in some way lowers the blood pressure—perhaps both centrally (myocardial) and at the periphery. Aortic stenosis is the only valvular defect associated with low blood pressure. If these grosser and more obvious causes are excluded, one must consider the patient who comes with the symptoms enumerated above, and in whom the tension seems to be abnormally low for him. The low pressure should be regarded as part of a state of general debility, and not stressed too much as an individual item. These patients are sometimes neurotic, and fasten upon their figures of low pressure, just as hypertensives are apt to brood on theirs. A phase of debility such as this may not uncommonly follow an influenzal infection. But often nothing definite is found. One must remember the possibility of early tuberculosis. The sedimentation rate might be noted. The reaction of the blood pressure to changes in posture should be studied, taking a reading with the patient lying and then at once when standing up. Addison's disease will be indicated as a rule by other symptoms before the blood pressure falls to 110 mm. Hg.

The rare state of postural hypotension is probably a lesion of the sympathetic nervous system, and the fall to 50 or 60 mm. Hg systolic on standing is diagnostic. It is also associated with impotence and lack of sweating; it is almost entirely confined to males.

The idiopathic cases of hypotension are often difficult to treat. After infection, the usual routine of convalescence should restore the normal. Where, as so often in these days, the patient is an elderly civilian, worn out with work and worry, and probably with a deficient protein intake, a period of rest and good food, followed by a holiday in pleasant bracing surroundings, would work a cure, but this is a counsel of perfection under present conditions. Often the appetite is bad, and for some patients a little alcohol is very beneficial (if they can get it). Drugs are probably least useful, unless the patient cannot get rest and change. Strychnine in full doses, pushed to the limit of tolerance, is undoubtedly valuable. Its faded reputation is largely due to small doses in unsuitable cases. The directly pressor drugs, ephedrine or paradrine, should be tried. Amphetamine is apt to stimulate the cerebral cortex too much, and may cause insomnia if taken late in the day. Amphetamine in the morning and ephedrine in the afternoon is a good combination. The camphor preparations are of doubtful value. Desoxycorticosterone acetate is not useful except in Addison's disease.

What is First-class Protein?

Q.—*Is any exact meaning attached to the phrase "first-class protein"? I have always taken it to indicate protein from an animal source, but would welcome an authoritative explanation.*

A.—The biological values of proteins may be measured on growing animals by the ratio of gain in weight to intake of protein, or, on adults, by the ratio of body nitrogen spared to food nitrogen absorbed. The values depend on the ratios of amino-acids in the proteins. The proteins of the endosperm of cereals contain little of some of the indispensable amino-acids: the protein of white flour, for example, contains little lysine; consequently their biological value is low. However, animal proteins can supplement these cereal proteins: for example, young rats grow as well on a mixture of equal parts of milk protein and wheat protein as on wheat protein alone. Even gelatin, which is an incomplete protein containing neither valine nor tryptophane, can supplement white flour by virtue of its high content of lysine.

The biological values of the proteins of legumes are intermediate between those of animal and cereal proteins, and they may be used to supplement the cereal proteins. The biological values of the proteins of plant cells are as high as those of the animal proteins, but their low concentration and the large amounts of cellulose in plants make them unsuitable sources of proteins for human beings unless they are concentrated in some way.

The term "first-class protein" is therefore relative: as commonly used it includes proteins from animal sources only.

Worms in Cod

Q.—*A worm is found in the cod which is about 1½ inches long, white, and turns brown in a refrigerator. A fish merchant states that it is always found in cod at this time of the year. (a) Is it a parasite of man? (b) Is it, and are its eggs, destroyed by cooking? (c) Is any treatment necessary after eating fish infected by it?*

A.—In the absence of actual specimens of the parasites it is not possible to identify them with any certainty. It is presumed, however, that the worm in question is a nematode, possibly belonging to the subfamily Cucullaninae, genera of which are found in various species of fish and, commonly, in the cod. It may be stated that they are not parasites of man, and that in any case both the parasites and their eggs, if present, would be destroyed by cooking. No treatment, therefore, is indicated in the case of human beings who may have eaten fish harbouring these parasites.

Order of Injecting Varicose Veins

Q.—*In the technique of injecting varicose veins, do you begin the course at the most distal or most proximal portion of the affected vessel, and what is the reason for doing so?*

A.—The lower two-thirds of the leg in varicose vein patients is a *locus minoris resistentiae* where ulcers, eczema, and chronic phlebitic and periphlebitic indurations are prone to develop. It is therefore unwise in well-established cases to inject the lower reaches of the leg, because a leakage here would become a chronic ulcer, and an excessive response a chronic periphlebitis and oedema; and if the disappointed patient gives up treatment these lesions would constitute a long-standing reproach. Furthermore, the treatment of the higher veins improves the condition of the lower part of the leg, so that it does not give trouble when its turn to be injected arrives. When the injections are an adjunct to ligatures, the order of injection from above down need not be observed. In cases of long previous femoral thrombosis in which varicose veins and complications have developed, the injections should be confined to the venous pools in the proximity of the complication; the injections should not be done systematically from above down as in straightforward cases.

"Boosting" Dose in Diphtheria Immunization

Q.—*I am immunizing children with A.P.T. as issued from the E.P.H.L.S. Many return for the second injection long after the recommended interval of four weeks. I should like to know: (1) Up to how many weeks or months is it efficacious simply to give the second injection of 0.5 c.cm. A.P.T.? (2) Is it more efficacious after a certain number of weeks to restart afresh with two injections properly spaced, and after how many weeks should that course be followed? (3) What is the recommended reinforcing dose to be given after four years? (4) Is a reinforcing dose of one prophylactic (e.g., A.P.T.) useful if the original prophylactic has been T.A.M. or T.A.F.?*

A.—The host's response to artificial immunization depends mostly on the adequacy of the primary stimulus: that is, the material used must be a good antigen, as A.P.T. is, and it must be given in adequate dosage. In this respect the custom of giving two doses of 0.2 and 0.5 c.cm. of A.P.T. might well be reversed to 0.5 and 0.2 c.cm., since the smallest dose of antigen will act as a secondary stimulus. In answer to the specific points: (1) If the primary stimulus has been adequate—e.g., 0.2 to 0.5 c.cm. A.P.T.—the second dose may be given as late as six months after the first and still evoke a good response. (2) After that period it may be wiser to give two spaced injections. The interval between first and second injections should not be less than one month, since, within limits, the longer the interval between injections the better the response. (3) The reinforcing or "boosting" dose need not be large: 0.2 c.cm. A.P.T. is adequate. (4) Yes: the antigen in any form will serve for the "boosting" dose; with older school-children T.A.F. is often recommended for the "boosting" dose, as being less liable than A.P.T. to produce reactions.

Neuritis after Typhus

Q.—*A colleague is suffering from intractable neuritis following typhus contracted in Australia 8 years ago. We do not see the disease in this country (New Zealand). The condition is resistant to all the usual methods of treatment, and appears to be getting worse.*

A.—Vascular lesions are characteristic of typhus, and it is possible, therefore, that the present symptoms are due to changes in the vessels giving rise to irritation of the perivascular sympathetic fibres, in which case treatment by local injections of alcohol or by sympathectomy might be considered. As, however, long-standing intractable neuritis due to typhus is unusual, all other possible causes of the symptoms should first be excluded.

Generalized Sweats

Q.—*Two women in the 50's have had severe generalized "sweats" for years. One passes urine after every "sweat." Remedies such as bromides and phenobarbitone, and endocrine treatment, fail to relieve. Laboratory investigations have given no assistance. So inconvenienced has one woman been that she has threatened suicide. The "sweats" are a colourless, odourless, painless, but profuse hyperhidrosis; in no way do they suggest "hot flushes" in either case. What can be done?*

A.—Although the ages of these patients do at first suggest an association between the sweats and the climacteric, this possibility is fairly definitely excluded by the fact that endocrine (presumably oestrogen) therapy had no good effect. The other circumstances of the cases suggest a neurasthenic basis for the sweating. Although the effect of amphetamine might be investigated, treatment on general lines—a prolonged holiday or change in environment and occupation, hydrotherapy, combined perhaps with some sedative such as luminal—offers the best hope.

Ozone in the Factory

Q.—*I am an industrial M.O. and my firm have been offered a machine which generates ozone (output not stated), which is said to reduce fatigue, destroy smells, increase oxyhaemoglobin, prevent transmission of colds, reduce oppression, and destroy bacteria, etc. Can you give any guidance?*

A.—In normal persons the olfactory threshold concentration for ozone is 0.015 part per million, and irritation of the respiratory membranes occurs with concentrations greater than 0.05 part per million. The recognized maximum permissible concentration in occupied rooms is 0.04 part per million.

The addition of tolerable amounts of ozone to the air makes no detectable difference to working capacity, resistance to fatigue, or various other bodily reactions.

Ozone in permissible concentrations can inactivate certain unprotected air-borne organisms, but when such bacteria are covered with a protective coating of organic matter, as in the sprays emitted during coughing and sneezing, ozone in permissible concentrations is without effect.

A just-detectable concentration of ozone can reduce the smell of body odours enough to allow of a 50% reduction in the amount of fresh air required for odour control, but lower concentrations are valueless. However, with a given output of ozone and a constant ventilation rate, the concentration of ozone varies widely according to the atmospheric humidity, so that sometimes the concentration may be undesirably high and at other times too low to be effective. Hence, until accurate means for controlling ozone concentrations are available the use of ozone in the air of occupied rooms should be discouraged.

Pneumoperitoneum and Pregnancy

Q.—*A woman aged 25 years has been treated for an apical lesion by pneumoperitoneum, began about 18 months ago. The lesion appears quiescent. The patient is now two months pregnant, and interference in the normal course of pregnancy is not warranted. How long should the pneumoperitoneum be kept up during pregnancy, and what procedure should be adopted immediately after confinement, assuming the patient went through pregnancy without ill effect?*

A.—The pneumoperitoneum will clearly have to be abandoned gradually as the uterus fills the abdominal cavity. The exact treatment will depend upon the size of the uterus, but after the fourth to fifth month the refills will probably need to be smaller and less frequent, and by the sixth or seventh month it will probably be safest to cease refills altogether. The pneumoperitoneum should be reinduced as soon as possible after labour.

Psychopupillary Reflex

Q.—*Please give a full account of the meaning of the term "psychopupillary reflex." What is the diagnostic value of its absence?*

A.—The psychopupillary reflex is the dilatation of the pupil that occurs on receipt of a painful stimulus, or at such an emotional stimulus as startle. Its specific absence has no particular neurological significance, but according to some authorities it is sometimes observed in schizophrenia.

INCOME TAX

Car Expenses

R.S.O. holds a hospital appointment and uses a car for (*a*) private outings, (*b*) travelling between his residence and the hospital, (*c*) inside the extensive hospital grounds, (*d*) travelling for the purpose of postgraduate education, and (*e*) official journeys to visit outlying hospitals—he receives a mileage allowance in respect of (*e*). What deduction can he claim for income-tax purposes?

*** No claim can be made for the expenses incurred under (*a*), (*b*) and (*d*). As regards (*e*) any claim would be restricted to the excess of the *necessary* expense over the allowance received, and that excess would probably be insubstantial. The use of the car under (*c*) would provide grounds for a claim, but only if the use of a car for that purpose is "necessary." On the whole, therefore, only a small proportion of the total mileage of the car will rank for an income-tax claim. As regards the expenses to be taken into account, they would include running costs, insurance, repairs, and depreciation.

LETTERS, NOTES, ETC.

Binocular and Monocular Vision

Dr. F. S. **Lavery** (Dublin) writes: In "Any Questions?" (July 28, p. 141) the answer given to the question under the heading "Binocular and Monocular Vision" would appear to me to have missed the point. The question brings forward a matter of considerable importance and should not be dismissed by an evasive answer. What is meant by the statement that few have centralized binocular vision is that large numbers of people when engaged upon tasks, such as reading, which require visual concentration hold the object gazed at towards the side of their dominant or master eye. It is wrong to say that it is this habit which produces the dominant eye. The dominant eye is part of the sidedness of an individual and cannot be changed. As a result of training many who are natively left-sided are taught to use the right hand for actions which should be performed by their dominant hand. In these people the left eye remains the dominant eye. As a result of investigations which I and others have carried out I am satisfied that the upset in cerebral dominance produced thereby causes many disturbances, amongst which is disability in learning to read. I would refer your querist, and anybody who is interested in the subject, to "Ocular Dominance" from the *Transactions of the Ophthalmological Society*, 1943. In this communication of mine will be found data in support of the above statement and descriptions of simple clinical tests for the condition.

Anatomical Nomenclature

Mr. R. **O'Rahilly**, M.B., Ch.B. (Department of Anatomy, University College, Cork) writes: The comments on anatomical nomenclature by Mr. A. Hollman (Sept. 22, p. 414) are long overdue. According to the Goodenough report it is most important that "the clinical teachers and the teachers of the preclinical subjects should co-operate in securing continuity in the curriculum and a proper dovetailing of their respective teaching, so that the student's progress through the whole of the medical course may be smooth and logical." This smoothness is at present ruffled by the retention of obsolete terminologies by clinicians. Anatomical textbooks are written in the B.R., and surely clinical textbooks designed for the same students should make use of the terminology with which the student is already familiar; at least the insertion of the newer terms in addition to the older names before displaying a new edition of a surgical or physiological textbook should not be too much to ask. In conclusion I would point out to Mr. Hollman that fortunately for future medical students some of us do not find anatomy such "an uninspiring subject."

Bruising and Rheumatism

Dr. Eli **Davis** (London, E.3) writes: Full justice has not been done to the question on the occurrence of spontaneous "bruising" in the rheumatic diathesis (Sept. 15, p. 375). The occurrence of rheumatic symptoms in the haemorrhagic diathesis is very well known, as stressed by your contributor. But it was because the tendency to spontaneous ecchymoses in the rheumatic diathesis was so little known that I stressed this feature in the evidence I presented in papers in the *Lancet* (1941, **1**, 146; 1943, **2**, 160). Persons suffering from rheumatic diathesis are specially prone to spontaneous ecchymoses. This purpura is practically always benign.

Artificial Respiration

Capt. M. **Hemming**, R.A.M.C., writes: While doing artificial respiration by Eve's rocking method recently in a case of drowning, I was impressed by the increase in depth of breathing which could be attained by means of compressing the thorax on expiration and completely removing pressure as the feet went down. We were using a stretcher on a trestle, which was placed almost under the chest and enabled the sides of the chest to be pressed together; this would not be so easy if the stretcher was suspended from above.

Car Without Foot Pedals?

Dr. H. B. C. **Sandiford** (Felpham) writes: The answer to Dr. Rammell is an electrically driven chair. They will go up to 30 miles and are most reliable. Only the hands are used.

Disclaimer

Dr. M. E. H. **Halford** writes: A statement attributed to me, in relation to the treatment of a patient of Maidenhead Hospital, was published in the *Sunday Express* on Sept. 30. This publication was made without my knowledge or consent. I have not, on any occasion, made a statement regarding the treatment of a hospital patient to the *Sunday Express*.

INDICATIONS FOR SURGERY IN PENETRATING WOUNDS OF THE CHEST

THE IMPORTANCE OF PULMONARY INJURY*

BY

G. QVIST, F.R.C.S.

Lieut.-Col., R.A.M.C.; Officer Commanding Surgical Division, 16 (Br.) General Hospital, M.E.F.

The most important object in treatment of injuries involving the pleura is early pulmonary re-expansion, since by this means pleural infection is limited and respiratory efficiency restored. Although this is well recognized and has been emphasized again recently (Thomas and Cleland, 1945), expansion of the lung, and in fact the pulmonary condition altogether, is usually regarded as a factor secondary in importance to the pleural lesion, and attention is focused mainly on haemothorax. It is one of the purposes of this communication to suggest that the prognosis of penetrating wounds is influenced as much by the condition of the lung as by that of the pleura.

It is a matter of experience that, on the average, expansion of the lung is slower after penetrating wounds than after non-penetrating injuries, quite apart from infection. This can be seen in a comparison of different types of haemothorax following these two varieties of chest injury; and is shown diagrammatically in Fig. 1. Thus in both haemothorax and haemopneumothorax pulmonary re-expansion is less rapid after penetrating wounds, while with total haemopneumothorax prognosis is good in the case of non-penetrating injuries; but after penetrating wounds the chances of persistent pulmonary collapse are high even in the absence of infection, and it is this type of case which calls most frequently for surgical evacuation of pleural haematoma. It is suggested that in most cases this difference is due to pulmonary injury which is not always recognized; and that treatment directed to the pleura alone therefore will not always result in re-expansion of the lung. It is significant that, with non-penetrating injuries, if there is difficulty in resolution of haemopneumothorax it is nearly always due to pulmonary injury with broncho-pleural fistula.

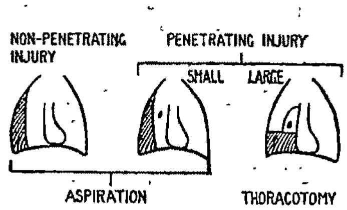

FIG. 2

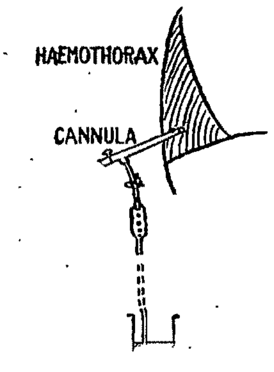

FIG. 3

FIG 1.—(i) Haemothorax. (ii) Haemopneumothorax. (iii) Apical or total haemopneumothorax.

FIG. 2.—Treatment of chest injuries.

FIG 3.—Aspiration of large haemothorax.

In addition to less favourable expansion of the lung after penetrating wounds, prognosis is worse also because of the greater risks of infection. Here again the presence of pneumothorax is an unfavourable influence and greatly increases the chances of pleural infection. The most important predisposing cause of empyema is the association of infected foreign matter and haemopneumothorax. If the lung is fully expanded, infection may not occur even in the presence of a large foreign body, and if it does it will be localized. Such cases are not uncommon, and it is to be assumed that the foreign body has entered the pleura without damage to the lung so that pneumothorax has not occurred and infection has been avoided or limited.

Elimination of the pleural space is of such significance that it is reasonable to regard early pulmonary re-expansion as even more important than avoidance of infection—first, because the former is a most useful means of promoting the latter, and, secondly, because the prognosis of localized basal empyema is much better than that of persistent total haemopneumothorax, even if this remains sterile.

With the majority of small penetrating wounds the chances of both pneumothorax and infection are small, and conservative treatment is usually justified. With large penetrating wounds, however, the amount of damage to lung and to chest wall makes both pneumothorax and infection almost inevitable, so that surgery is essential. Thus we can summarize the main principles of treatment of penetrating wounds as: (1) early elimination of pneumo- and haemo-thorax, and (2) early surgical toilet of large wounds of the lung and pleura.

There are three zones at which treatment may be necessary—forward, base, and at home. The last includes late removal of foreign bodies and treatment of chronic empyema, and will not be discussed here.

Treatment in the Forward Zone

Apart from special wounds involving the diaphragm or pericardium and primary haemorrhage, there are two groups of penetrating wounds, large and small, from the point of view of treatment. The former require operation, while the latter should be included for treatment with non-penetrating injuries as *simple haemothorax* and treated by aspiration (Fig. 2).

---

* Paper presented at the Allied Military Surgical Conference in Paris on July 25, 1945.

Indications for Operation

Decision on the need for operation is often difficult, and must be made on the individual case. As a general rule, however, it can be said that if a penetrating wound is larger than about 1 cm. it will probably need operation. If there is a pneumothorax as well, the necessity for surgery is almost certain, because there is enough damage to the chest wall or to the lung, or to both, to endanger life or to render infection probable. If there is no air in the pleura the pulmonary lesion will be localized and the outlook favourable; the best prognosis in penetrating wounds of the lung and pleura is undoubtedly in those cases in which there is an adherent pleura.

While there are numerous recognized indications for operation, such as the presence of a sucking wound, compound fracture of rib, retention of a large foreign body, or a large wound of the chest wall, these nearly all depend for their surgical importance on the existence of conditions in which pneumothorax is likely, which in practice are provided by a wound larger than about 1 cm. in the visceral or parietal pleura. If the pleural wound is smaller than this it will be blocked by haematoma or muscle, and none of these indications for operation will arise. In this type of case little is to be gained by wound excision, whereas there are operative risks such as the undesirable initiation of pneumothorax by disturbing the wound, and increase in size of haemothorax due to rise in blood pressure under anaesthesia.

If the pleural wound is larger than 1 cm. it usually means that there is also a fractured rib or sucking wound with potential or actual pneumothorax, or a large wound of the chest wall, for any of which surgery is necessary. Prognosis in such cases depends above all on the amount of pulmonary damage. It has been pointed out that open pneumothorax is often tolerated very well—as, for example, with thoracotomy under local analgesia—and that some patients from Dunkirk were alive five or six days after injury in spite of an open wound of the pleura (Barrett, 1940-1). The explanation is probably to be found in the absence of pulmonary injury: a sucking wound is much less serious if the pneumothorax is due to injury of the chest wall alone than if there is also a broncho-pleural fistula.

The size of the pulmonary wound is thus important as an immediate danger in the production of pneumothorax. In addition it is also of great influence later in the development of infection or delayed pulmonary expansion, so that adequate surgical toilet is essential for such wounds.

Indications for Aspiration

Treatment of small penetrating wounds is by aspiration of haemothorax and instillation of intrapleural penicillin. While this does not need discussion here, there are two practical points which are of importance in the forward area. These are: (*a*) Selection of the most urgent cases for immediate treatment, while others may be evacuated to the base hospital. The case with displacement of the apex of the lung requires aspiration more urgently than one with haemothorax limited to the base, because the prognosis of persistent apical haemothorax is very much worse. (*b*) Employment of the most rapid method of treatment with the minimum of apparatus. It is convenient to aspirate small effusions with a syringe and two-way tap, and large effusions by means of a blunt aspirating cannula or wide-bore needle attached to a water-seal bottle. A large A.P. refill needle is satisfactory, and the flow can be regulated at a steady drip by means of a standard blood-transfusion drip connexion (Fig. 3). The use of general anaesthesia, suction bottles, or laborious aspiration with syringe is usually not necessary. In this way the minimum of attention is required—a point of some importance to the busy C.C.S. physician—and several cases may be dealt with at the same time, the only really essential apparatus being a sufficient number of suitable needles.

Treatment at the Base

There are two conditions which call most often for treatment at this level—viz., delayed pulmonary expansion and infection.

1. Delayed Pulmonary Expansion

Expansion of the lung may be delayed by the condition of the pleura or of the lung; the former usually receives the maximum of attention as the problem of the unresolved haemothorax; but probably the latter, the condition of the lung itself, deserves as much care.

(i) *Unresolved Haemothorax.*—If aspiration fails to eliminate haemothorax within two weeks, surgical evacuation of the haematoma must be considered in order to avoid pleural fibrosis with an incompletely expanded lung. It is important, however, to select only the cases in which this is essential. The prognosis of persistent apical haemothorax is very much worse than that of basal haemothorax, because pulmonary efficiency is much poorer with collapse of the lung at the apex than at the base. In fact, the outlook for a sterile apical haemothorax is worse than for a basal empyema so far as final function is concerned. Hence, if the apex is well expanded there is no need for early surgical evacuation of the basal haematoma, and in fact such treatment is dangerous, because thoracotomy involves pneumothorax with the possibility of apical collapse. It is wiser to defer operation in order to ensure firm union of the pleural layers at the apex. On the other hand, if aspiration of haemothorax with collapse of the upper lobe is proving difficult, evacuation of the haematoma should be carried out as soon as possible.

(ii) *Pulmonary Contusion.*—If the lung is uninjured its re-expansion will be hindered only by the pleural contents, as in the majority of non-penetrating injuries. But if there is a pulmonary contusion or laceration, this will delay re-expansion, quite apart from the state of the pleura. It is significant that the problems of unresolved haemothorax arise almost exclusively in penetrating wounds, suggesting that it is indeed the pulmonary injury which is vital, so that "delayed pulmonary expansion" is probably a better term than "unresolved haemothorax" for this condition. Inasmuch as its extreme vascularity makes the lung very resistant to infection, it also renders the pulmonary tissue extremely liable to contusion after injury, although in comparison with the more dramatic responses of the pleura this tends to escape notice. The effect of pulmonary contusion is to cause obstruction to the air-passages and thus lead to atelectasis of lobar or lobular type. Pulmonary re-expansion will then be slow and may even be incomplete. It will be found in nearly every case of haemothorax in which the lung does not re-expand easily that there has been penetration or perforation of the pulmonary tissue by the missile. Further, in refractory apical haemothorax the injury is nearly always of the upper lobe, with the result that the apex has not re-expanded. These cases can be contrasted with the non-penetrating chest injury where without pulmonary damage (or only superficial damage) aspiration of haemo- or pneumo-thorax is almost invariably followed by rapid and complete pulmonary re-expansion. Thus it is suggested that pulmonary contusion or laceration is the main cause of slow or incomplete pulmonary re-expansion following penetrating wounds.

Pulmonary contusion due to penetrating wounds is a condition well recognized in the absence of pneumothorax. The prognosis is usually good and resolution occurs fairly rapidly. But if a pneumothorax were initiated in such a case, the condition would be very similar to that in delayed re-expansion under discussion. It is a matter of common experience in chest disease that, in the presence of partial bronchial obstruction due to any pathological process, initiation of pneumothorax will often precipitate total atelectasis, which is difficult of resolution. This is seen commonly in tuberculosis and neoplasm, while it has been shown that, in atelectasis following lobectomy, resolution occurs very much more rapidly in the absence of a pneumothorax (Sellors, Thompson, and Qvist, 1944). In a comparable way, therefore, haemorrhage into the lung after injury might be expected, owing to interference with the air-passages, to show this lethargy in re-expansion in the presence of a pneumothorax.

Looked at from another aspect, it would be very surprising if, after penetrating wounds, there were no cases intermediate between immediately fatal lacerations and small contusions of the lung. It seems much more likely that it is just these cases of refractory haemothorax which represent the badly injured lungs that have survived but are in a state of contusion unfavourable to adequate aeration, and in point of fact the vast majority of these difficult cases of haemothorax are severe penetrating and perforating wounds of the lung. If, even with the best treatment, some lobes never re-expand completely, it is not always the treatment that must be blamed, but the original injury, in the same way as loss of function of a limb may be determined by severe injury.

There is an interesting parallel to be found between the recognition of the relative importance of pleura and lung in haemothorax following trauma and that following lobectomy. In the earlier days of lobectomy delayed pulmonary expansion was regarded as secondary to pleural changes, but in 1939 it was pointed out by Tudor Edwards that pulmonary collapse was in fact the primary lesion in such cases. It is suggested that, in penetrating wounds similarly, the pleural condition is of secondary importance, and that injury of the lung is the main cause of delayed pulmonary re-expansion.

From the above considerations it would seem that treatment should be directed to both pleura and lung. If the apex of the lung is still unexpanded after 14 days, surgical evacuation of the pleural haematoma should be carried out. The object of this is to avoid pleural fibrosis so that subsequent expansion of the lung is not impaired.

Surgical evacuation of the pleural contents alone, however, would not always be expected to result in complete pulmonary re-expansion if there is also a contusion of the lung—which has in fact been borne out by experience of the operation. Treatment must be directed to expansion of the lung, and the most promising method at present is probably by suction. This method has been described recently by Thomas and Cleland (1945), and good results reported by the use of decortication, followed by suction for three or four days, using apical and basal pleural catheters.

The value of decortication is debatable. According to Thomas and Cleland (1945) it is important to perform radical operation to mobilize the whole lung, while this is not regarded as important by Sellors (1945). It would seem that such differences of opinion might well be explained according to the stage at which operation is undertaken. If surgical evacuation of haemothorax is carried out within two or three weeks of injury decortication should not be necessary. If, after evacuation of the haematoma and adequate post-operative drainage, preferably with suction, the lung does not expand, then re-expansion would probably not have occurred even if decortication had been performed, because the cause of delayed expansion is in the lung itself after its laceration and not in fibrosis of the visceral pleura. If surgical evacuation of the haematoma is delayed more than four weeks, then decortication may have a place in treatment; but again prolonged post-operative suction drainage is probably more important, even if such extension of drainage means development of secondary empyema.

2. Infection

The rate of infection of haemothorax following penetrating and perforating wounds has been given as 21.9% (Tudor Edwards, 1943) and 33% (Nicholson and Scadding, 1944). In 400 such cases at a chest centre in the B.L.A. empyema occurred in less than 14%. Considering that these cases of haemothorax included particularly those which were not progressing well and those which were already infected, it suggests that the figures of infection usually given are inclined to be rather too high. This is very likely, since a large number of simple haemothorax cases resolve rapidly with aspiration in the general base hospitals and never find their way into chest units, so that these good results are not included in the estimate. It seems likely, then, that infection in haemothorax after penetrating wounds is not more than 14%. Apart from this apparent decrease in infection rate, there is probably also a real diminution due to the prophylactic use of penicillin and to more adequate early treatment in the forward areas both in elimination of haemopneumothorax and in surgical toilet.

The association of haemopneumothorax with infected foreign material is the most common cause of empyema, so that the two essentials in prevention are early pulmonary re-expansion and adequate surgical toilet. Penicillin therapy is of value in prophylaxis, but is second in importance to radical surgery in the elimination of potential infection. Once infection has occurred it is best to carry out drainage immediately, since penicillin therapy for infected haemothorax is rarely successful, and its continued use leads to pleural fibrosis and loculation.

Infection of the chest wall is of small importance in the absence of pleural damage. If there is a communication with the pleura, however, the condition is serious, since there is always an associated empyema and the patient suffers from toxaemia and open pneumothorax. This condition is seen most commonly with wounds of the anterior chest wall, where anatomical conditions favour infection, since the costal cartilages show poor resistance and there is often difficulty in closing a wound after adequate excision owing to lack of available muscle. There is always an associated empyema, and often contusion or atelectasis of a section of injured lung, which is usually the upper lobe corresponding to the anterior wound.

Treatment consists in the first place in prevention of sepsis by adequate excision of wounds, particularly those in the region of costal cartilages. With established sepsis and a secondary sucking wound, the first step is drainage of the empyema with temporary packing of the wound. The general condition usually improves considerably, after which secondary closure with muscle flap is carried out.

Infection of the lung is nearly always associated with empyema, and as a rule takes the form of a superficial infection with secondary sloughing into the empyema cavity. Abscess of the lung without empyema is rare, since pulmonary injury large enough to produce suppuration will also result in initial pneumothorax. Surgical treatment for pulmonary infection following injury is therefore usually incidental to the treatment of empyema, and is limited to the removal of sloughs or foreign bodies through the empyema tube.

Summary

The prognosis of penetrating wounds is worse than that of non-penetrating injuries because pulmonary re-expansion is slower and pleural infection is more likely.

Pneumothorax is of great significance in penetrating wounds and has an unfavourable influence both in the occurrence and resolution of infection and in the resolution of pulmonary contusion.

Pulmonary contusion and laceration are important causes of delayed expansion of the lung and are nearly always found in the condition of unresolved haemothorax.

Penetrating wounds of the upper lobe have the worst prognosis and are nearly always present with total or apical unresolved haemothorax.

If apical haemothorax persists for more than two weeks surgical evacuation is indicated, but this is contraindicated for basal haemothorax.

After surgical evacuation of haemothorax complete expansion of the lung may still not occur owing to residual pulmonary damage. Treatment for this condition is unsatisfactory, and the best at present is probably prolonged pleural drainage, preferably with negative pressure. Decortication is probably of value in late cases.

Infection of haemothorax following penetrating and perforating wounds occurred in less than 14% in 400 cases.

I should like to point out that most of the clinical experience on which this paper is based was obtained at a Chest Centre in the B.L.A., in which responsibility was shared with Major N. Lloyd Rusby, R.A.M.C., and Captain (Miss) Joan Cheale, R.A.M.C., to whom my thanks are due—to Major Rusby especially for the views expressed on the significance of pulmonary injury.

Rubber hot-water bottles will soon be on sale to the general public, but as four years' accumulated demand cannot be met at once sick persons or expectant mothers should continue to present a medical certificate and the shopkeeper will immediately obtain a hot-water bottle from his usual supplier. Maximum prices will be 7s. 2d. or 8s. 3d., including purchase tax, according to size, and, for hand-made bottles, 12s. 11d.

OUTBREAK OF EPIDEMIC DIARRHOEA AND VOMITING IN A GENERAL HOSPITAL AND SURROUNDING DISTRICT

BY

GEORGE BROWN, M.B., F.R.C.S.Ed.
Medical Superintendent

G. J. CRAWFORD, M.D., B.Sc., M.R.C.P., D.P.H.
City Pathologist

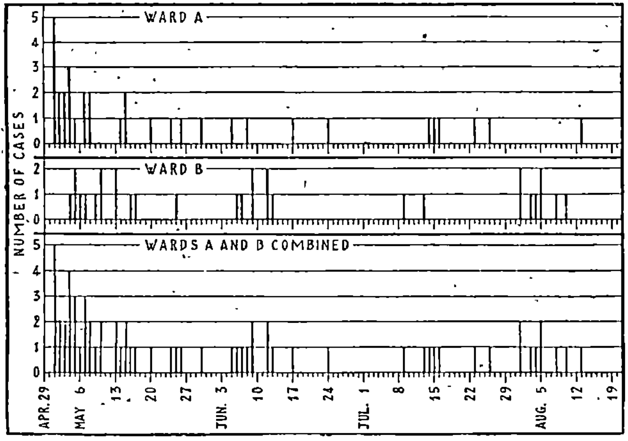
AND

LOIS STENT, M.D., Dip.Bact.
Assistant City Pathologist

Hope Hospital, Salford

The hospital in question is a general hospital of 1,000 beds with a nursing staff of 365, and serves a compact, densely populated industrial area. Attention in the hospital was first drawn to the outbreak on May 1, 1945, when five babies in a maternity ward, whose ages ranged from 3 to 6 days, were reported to have developed diarrhoea. The maternity ward in question ("A") consists of 20 beds and 20 cots. It is the ground-floor ward of a block of three maternity wards, the second ward ("B") consisting of 22 beds and 22 cots on the first floor, and the third ward ("C") consisting of 24 beds and 24 cots directly above. These wards are separate structurally from each other, but the nursing staffs are in contact at meal-times, lecture-times, etc., and the same medical staff serves both wards. There are 10 nurses on each ward.

On inquiry it was found that two cases of diarrhoea had been admitted previously to a surgical ward as suspected acute abdominal conditions, but no trace could be discovered of any contact with the babies in Ward A, which was far distant from the surgical ward. The cleaner of Ward A had had some diarrhoea on April 13, 1945, and she would have been in the nursery as part of her normal duties, although she would have no direct contact with the babies. On May 2 the sister of Ward A and another baby developed symptoms, and on May 3 another member of the nursing staff and one of the mothers on the same ward had diarrhoea. On May 4 a third nurse, a mother, and a baby in Ward A were affected, while a baby in Ward A developed the condition. On May 5 a member of the medical staff reported an attack of diarrhoea, while a mother in Ward A and two babies in Ward B were also reported. After this initial outbreak there occurred a succession of fresh cases in both wards, involving members of the nursing staff, mothers, and babies, and in the succeeding 15 weeks a total of 7 nurses, 11 babies, and 17 mothers had been affected in Ward A, while the figures for Ward B were 3 nurses, 11 babies, and 17 mothers. During this length of time there were two intervals of 20 days and 18 days (Ward A) and two of 26 and 18 days (Ward B) during which no cases occurred (see accompanying histogram).



The total admissions to these wards over the same period were 209 mothers and 184 babies to Ward A and 135 mothers and 132 babies to Ward B. During the whole period of 15 weeks there was not a single case of diarrhoea reported in patients or staff in the third maternity ward (Ward C), adjoining the other two and bearing an exactly similar relationship in regard to nursing and medical staff.

Four patients admitted to the ante-natal ward reported symptoms which had in each case developed before admission, and one of these patients subsequently gave birth to a child who developed diarrhoea on its second day of life. Sixteen other patients were admitted to the general wards with similar symptoms, while 9 patients already in the general wards of the hospital became affected. Seventeen further cases occurred in nurses working in the general wards of the hospital, and it is possible that further members of the nursing staff may have had mild and transient symptoms which were never reported. During the fourth and fifth weeks there was an outbreak of Sonne dysentery in the hospital; 20 cases occurred in one ward, in 14 of which the diagnosis was confirmed bacteriologically.

It was soon apparent in respect of the young babies that this outbreak in no way resembled in severity a previous epidemic of neonatal diarrhoea which had occurred in the maternity wards at the beginning of the year, and which had been associated with a high mortality. Moreover, on that occasion no adults had been involved. Of the total of 111 cases in the present series, 20 adults were admitted to hospital with a history of symptoms, and the remaining 91 cases (including 27 members of the nursing staff and 22 babies) acquired the condition in the hospital. Daily visiting to the patients provided a constant contact with the outside community, and in several instances histories were available of other members of the family suffering from diarrhoea and vomiting about the same time. The possibility of infection having been brought in from outside cannot be entirely ruled out, but the fact that 65 of the cases occurred in two neighbouring wards points to a degree of local spread within the hospital, yet it should be noted that Ward C remained entirely clear. Careful inquiry failed to throw suspicion on any foodstuff, milk, or water supply as a possible source of infection.

Clinical Features

There were no noticeable prodromal signs; the onset of the condition being ushered in by diarrhoea and perhaps abdominal pains, but in a few cases there were preliminary feelings of malaise and general discomfort, not unlike the onset of an attack of influenza.

Diarrhoea was the main symptom and also the most constant, usually being the first to appear and the last to clear up. It was present in every case, and sometimes was the only material complaint. The number of stools in 24 hours varied from 4 to 22. The diarrhoea was characterized by profuse loose watery stools which were invariably negative to bacteriological examination. No blood or mucus was present, except that the babies' stools tended to become green and contain mucus. At the onset the stools of the babies were also typically watery and seemed to soak into the napkins. Abdominal pain was not constant, and was present in 45 out of 89 adults (50.5%). It varied considerably in severity, and in 5 cases was so severe that the patient was admitted as a suspected abdominal catastrophe, with a tender rigid abdomen and generalized pains. This feature was limited to patients admitted from outside, and none of the cases occurring in the hospital and coming rapidly under observation and treatment showed such severe abdominal signs. Nausea and anorexia were present in practically all the adults—the nausea being pronounced in 25 (28.1%); but vomiting was found in only 46 cases of the total of 111 (41.4%), affecting 42 adults (47.2%) and 4 infants (18.2%).

Pyrexia was present in 32 out of 89 adults (34.8%) but in none of the babies. In every such case it was under 100° F. and of brief duration, usually 24 to 36 hours. There was one exception, however—a boy aged 15 who had a sustained temperature up to 102° F. over a period of some 10 days, and who was admitted as a suspected case of peritonitis. In this particular instance there was a history of 6 other members of the family having suffered from diarrhoea and vomiting at home. It is interesting to note that out of 37 mothers affected, 24 (63.3%) had a pyrexia of brief duration which never exceeded 100° F., thus giving a higher incidence of pyrexia than any of the other groups.

Vertigo was not found, but in 10 adults (11.2%) there were severe headaches. Injection of the fauces was not a feature of any of the cases. Two cases were admitted in a state of collapse with well-marked dehydration, which responded quickly to treatment. None of the patients could be regarded as dangerously ill, although in 7 the illness was of a considerable degree of severity. The average duration of symptoms was 4.6 days, the shortest being 24 hours and the longest 14 days. With the babies they averaged 4 days, the mothers 3.1 days, members of the nursing staff 6.1 days, and cases admitted from outside, which might be regarded as the more severely affected of those occurring outside, 7.3 days. There were no relapses during the period of observation. Except for the babies in the maternity wards the age incidence varied from 1 year 3 months up to 84 years, most of the patients being in the young adult group.

In general the patients in the maternity wards—the babies and the mothers—were the least severely affected. The weight charts of the babies presented a very typical appearance, the onset of the symptoms being associated with a loss of weight which varied from 2 to 21 oz. and which averaged 13 oz. This loss of weight usually occurred during the period when the weight of the baby was climbing back to the birth weight after the customary initial fall. The appearance of a sharp fall in the rising curve was very characteristic. As soon as the symptoms cleared there was a rapid improvement and the baby very soon regained its lost ground. The condition of the babies did not give rise to anxiety at any time. As a rule, it was not necessary to retain mothers or babies in hospital longer than the normal period, and this occurred only when the symptoms appeared shortly before the usual expected date of discharge. The delay was never significant. In 8 cases the mother of an affected baby subsequently developed the condition, the average interval being 4.4 days. In only one case did the baby develop symptoms after the mother, that being the one already mentioned, in which the mother had diarrhoea and vomiting before admission to the ante-natal ward and the baby developed loose stools on its second day after birth. In 28 cases the mothers were affected while the babies remained perfectly well, and in 13 the babies were involved and the mothers remained clear. The babies were all breast-fed, but during the first few days of life were given sterile water with sterile precautions.

Treatment of the adults was on simple empirical lines—rest in bed, fluid milk diet, and a simple bismuth-and-chlorodyne mixture being given as a routine. Thirteen members of the nursing staff were also given sulphaguanidine, but there was no evidence that this affected the course of the illness in any way. Most of the symptoms cleared quickly as soon as the patient went to bed, the diarrhoea being the most persistent and lasting throughout, gradually lessening in severity. In a few instances the abdominal pains remained for several days, but were usually associated with the most persistent cases of diarrhoea.

Investigation by Questionary

Sonne and Flexner dysentery have been endemic in the surrounding area for several years, and occasionally small outbreaks have occurred in the hospital, in the day nurseries, and also in the district. These outbreaks have been easily identified bacteriologically, the numbers notified have not been large, and the general practitioners accept them as part of their usual routine. During the past few months it was noted that a large proportion of the stools sent in from practitioners were negative; some practitioners who sent in stools regularly for examination commented on this and also stated that they were having large numbers of cases attending their surgeries with an unusual type of acute diarrhoea, sometimes preceded by vomiting. The cases were so numerous that they did not attempt to have more than a fraction of them examined bacteriologically. When the hospital outbreak occurred and had been systematically investigated from the laboratory standpoint, with negative results as described above, the following questionary was sent to 20 of the principal Salford practitioners, who had been established in different parts of the city—population approximately 160,000—for at least several years before the war. Of these, sixteen replied, and their answers are summarized after each question. Extra faeces outfits were also forwarded to each practitioner, with a request to send in fresh samples of faeces from any further cases they might have.

1. *Have you had an outbreak of gastro-enteritis in your practice?*—Sixteen replied, "Yes."

2. *Can you give any idea as to when it began?*—Early 1944, 1; autumn, 1944, 3; Feb., 1945, 1; March, 1945, 1; April or early May, 1945, 9; not stated, 1.

3. *When did it abate?*—June, 1; July, 11; end of July, 2; not stated, 2.

Inquiries from practitioners at the time of writing—Aug. 25, 1945—show that there has been no recrudescence of the epidemic, but that sporadic cases are still occurring, sometimes in groups of two or three. Several practitioners thought there had been two or three waves of infection during April, May, and June.

4. *Does this appear to be a new type of infection?*—Yes, 13; cannot say, 1; unanswered, 1; had seen similar outbreak, but not so severe or lasting so long, 1.

5. *General symptoms and duration of the disease.*—A large majority stressed the sudden onset of profuse watery diarrhoea, sometimes with colic and often preceded by nausea and vomiting. Occasionally there was slight pyrexia, usually clearing up in 2 to 5 days but sometimes lasting 10 to 12 days. A few cases had relapses. Profuse watery diarrhoea was the outstanding symptom in nearly all cases—stools 5 to 20 a day. Two practitioners stated that they had occasional mild cases with nausea and vomiting without diarrhoea. Only one practitioner mentioned giddiness in a few cases after severe attacks.

6. *Can you express any opinion as to whether this type of gastro-enteritis is different from the usual cases of bacillary dysentery which have been in evidence for some years?*—Fourteen replied, "Yes": mainly on account of sudden onset, nausea and vomiting being much commoner, and also because of a profuse watery stool, occasionally with mucus but very rarely blood.

7. *Age incidence.*—All ages affected, 9; mainly adult, 6; not stated, 1.

8. *Does it usually spread to other members of the family?*—Yes, 13; very rarely, 1; usually no, 1; no, 1.

The general impression was that it occasionally spread to all members of the household, usually at intervals of 2 to 4 days, but sometimes as long as 7 days. As a rule it did not spread to all members, but picked out a portion of them. As stated above, six of the practitioners considered that adults were definitely more often affected than children. It was admitted that many of the adults who attended the surgeries came for sick notes. This may be the explanation, as affected adults would therefore be more in evidence than children.

9. *Any other observations that strike you.*—No respiratory symptoms mentioned. No mention of fatal cases. Most practitioners agreed that the epidemic began insidiously with sporadic cases.

The number of new cases seen by each practitioner varied from 3 to 4 a day in some practices to as many as 15 to 20 daily in others while the epidemic was at its height—mainly during May and June. Four of the practitioners who replied to the questionary had themselves been infected. Inquiries were made at the maternity and child welfare clinics, day nurseries, and school clinics for evidence of increased incidence of diarrhoea and vomiting.

The maternity and child welfare clinics reported no increase of diarrhoea and vomiting in the babies attending. The day nurseries, which are kept under careful observation for outbreaks of dysentery, also reported no increased incidence during the period of the epidemic, although a few cases occurred among the adult staff. The impression at the school clinics was that there had been a slight increase in the incidence of gastro-enteritis.

Commentary

One may gather from this inquiry that the outbreak was fairly extensive, as probably only a portion of the cases affected reported for treatment. From reports received we have good reason to believe that a similar type of diarrhoea and vomiting has been widespread over the country this spring and summer. A comprehensive field inquiry into this would be of interest. An interesting feature of the outbreak is the observation that 13 out of the 16 practitioners stressed the fact that they could not remember a similar epidemic of gastro-enteritis occurring in their practices, and considered it a new type of infection. We cannot recall a similar outbreak at the hospital or in the surrounding district during our period of residence here—over 17 years.

Epidemic nausea and vomiting occurring in an English boarding school was described by Miller and Raven (1936). They mention similar outbreaks in Denmark in 1935. Diarrhoea was not a feature in these cases. A more recent outbreak is reported by Bradley (1943) in which some of the cases had diarrhoea as a symptom of minor importance. R. E. Smith (1938) mentions small attacks of epidemic vomiting and diarrhoea occurring at a public school; he states that cases tend to occur in the early morning, that they are of extremely short duration, and that vomiting is a more constant feature than diarrhoea.

The only description we have found of an outbreak in this country closely resembling the present one is that of A. H. D. Smith and Davies (1941) of gastro-enteritis at a large Army training centre. The disease appears to be common and widespread in the United States. Reimann *et al.* (1945) give a very full account of the disease as it occurs in America, with a comprehensive bibliography of outbreaks in other countries, and state that the transfer of infection to human volunteers by inhalation of filtered nasopharyngeal washings and faecal filtrates from patients has given encouraging results. Their clinical and epidemiological descriptions correspond closely with ours. We quote the following extracts from their paper:

> "This disease affects all ages, and its mortality is *nil*. Published epidemiological and clinical descriptions are similar. Sporadic cases are noted in the community for weeks or months, and eventually large outbreaks occur. No age group is immune, but children of school age and young adults seem mostly affected. Epidemics occur at all seasons of the year, but especially in the autumn; and in different groups from 15.1 to 100% of persons are involved. Incubation period has been estimated from 30 hours to 7 days, usually two days.
>
> "Epidemiologically the mild widespread disease with isolated cases and family and community groups involved, its apparent pandemicity, and seemingly short incubation period closely resemble the behaviour of the common cold or influenza, except for its spread over two or three months and absence of peaking. It is probably an air-borne infection, but hand-to-mouth or other means of transmission cannot be excluded, nor is it known whether it enters through the respiratory or alimentary tract."

We have little to add to this description and these conclusions concerning the disease. Examination of the stools from the hospital and practitioners for organisms and parasites and pus cells was completely negative. Stools were plated on desoxycholate citrate agar, MacConkey's agar, and in some cases on blood agar. When the hospital outbreak occurred a number of the stools which had been left in the refrigerator, and also some which were fresh the same morning, were sent to the Public Health Laboratory, Cambridge, for confirmatory examination, with negative results. Blood counts and serological tests were not done on any of the cases, nor was the vomit examined. No attempt was made to transmit the disease to volunteers.

We are unable to explain why the outbreak in the hospital was mainly confined to two maternity wards, the remaining adjacent maternity ward escaping completely. It may be argued that this was a different type of infection from the concurrent epidemic, but the identity of clinical symptoms and absence of detected infective agents in faeces, food, or water do not support this view.

Reimann states: "It is unknown at present whether or not the syndrome is related to severe epidemic diarrhoeal disease of the newborn. In most reports of the latter disease emphasis is placed on the absence of obvious infection in adults associated with the infants either before, during, or after an outbreak and on its high mortality." Similarly, in our cases the mildness of the outbreak among the newborn babies with concurrent infection among the mothers and staff definitely suggests that this is a different type of infection from the usual virulent type of neonatal diarrhoea.

The suggestion made by various authors (Reimann) that the disease is primarily an infection of the central nervous system is interesting. There were no definite nervous symptoms or sequelae in any of the hospital cases. In answer to the questionary only one practitioner mentioned giddiness as a sequel in a few of the severe cases. He suggested that this was cardiac in origin. Three others stated that mental depression after an attack was pronounced.

Summary

An outbreak of epidemic diarrhoea and vomiting of unknown origin is described.

Epidemiological data and previous published work suggest that the infection is due to a virus.

We cannot recall a similar epidemic in this area during the past 17 years.

We believe the outbreak has been widespread over the country.

A field inquiry to determine its extent would be of interest.

We wish to thank all the general practitioners who co-operated so well in supplying much of the data for this paper, also Miss Matthews, supervisor of the maternity department, for her assistance; Dr. J. L. Burn, medical officer of health for Salford, for assistance in making inquiries from the practitioners and at the various public health departments; and Dr. R. Cruickshank, pathologist, North-Western Group Laboratory, London, for valuable suggestions.

TICK-BORNE RELAPSING FEVER IN CYPRUS

BY

R. C. WOOD, M.B., Ch.B., M.R.C.P.Ed.
Major, R.A.M.C.; Medical Specialist, a General Hospital, M.E.F.

AND

K. C. DIXON, M.B., B.Chir., Ph.D.
Major, R.A.M.C.; Pathologist, a General Hospital, M.E.F.

The occurrence of several cases of relapsing fever in rapid succession after military exercises, in which the patients had passed the night in caves or dungeons, raised the possibility of the infection being conveyed by ticks. Further cases with a similar history have since come under our care. As tick-borne relapsing fever has not previously been reported in Cyprus, the details of these cases are described below.

Site of Infection

Infection occurred in caves and dungeons situated in the north and north-east of the island, of which the following is a description:

Cave A is partially subterranean, the mouth being screened by sandbags. It accommodated three men on guard. Its walls are soft and deeply and irregularly creviced. Ticks of the species described below were found in material scraped from the walls of the cave by Major J. Clark and ourselves. Dead ticks of this same species were found in spiders' webs attached to the roof of the cave. Cases 1, 2, and 3 slept in this cave 8 to 9 days before contracting relapsing fever.

Dungeon B is situated in the interior gallery system of extensive mediaeval fortified ramparts. Its walls are of hard masonry with many deep interstices in their surface. Scrapings from its walls were superficial and no ticks could be obtained. Cases 4 and 5 and probably Case 6 slept in this dungeon a few days before contracting the disease.

Cave C is artificially constructed in the side of an eminence composed of hard clay. Ticks could not be found in this cave, but considerable alterations had taken place in its structure before it was possible to make a search. Case 7 slept in this cave some 6 weeks before diagnosed as having relapsing fever.

Cave D is very similar to Cave A. It is situated about a quarter of a mile west of Cave A. A tick of the same species was found in scrapings from the roof of Cave D. Case 8 worked in a hut, the door of which is situated 10 yards from the mouth of Cave D. Case 9 slept in the open on several occasions in this area.

Cave E is within 12 yards of a trench in which Case 10 was digging shortly before he became ill. Identical ticks were found in this cave by Major J. Clark, who has kindly shown them to us.

Cave F is similar to Caves A and D. This cave is in a very inaccessible position and no ticks could be found during the somewhat cursory search possible in the time at our disposal. Cases 11 and 12 slept in this cave 9 days before reporting sick.

Vector of Infection

The ticks found in Caves A, D, and E were all of the same species—namely, *Ornithodorus tholozani*[*] (see Fig.). This tick is a known vector of relapsing fever in other parts of the Levant, but has not so far been described in Cyprus. There is direct evidence of Cases 1, 2, 3, 8, 9, and 10, before contracting the disease, being associated with places infested by this tick. Cases 4, 5, 6, 7, 11, and 12 equally well give a history of having spent time in places likely to be infested by the tick, although in those places it was not possible to recover it, doubtless owing to the natural hazard of such search. No lice were found on any of the patients in this series of cases. It seems reasonable to assume that the disease was conveyed by ticks acting as an intermediate host for the spironema* and that tick-borne relapsing fever is thus harboured by this vector in Cyprus.

---

[*] These ticks have been identified as such by Prof. Adler and Major Leeson.

Ornithodorus tholozani. (×12.)

Description of Cases

Case 1.—Unit A; slept in Cave A on 4/3/42. Patient was bitten by insects during the night. Reported sick 12/3/42, suffering from headache and repeated shivering attacks. This was first thought to be the result of T.A.B. inoculation on 10/3/42. Admitted to hospital 24/3/42. Temperature 103°. No lice in clothing, but marks of insect-bites on legs. Spironema found in blood film on 24/3/42. On 25/3/42 specimens of blood and C.S.F. were obtained and 0.6 g. novostab was given intravenously. In spite of treatment he relapsed on the following dates: 16/4/42—T. 104.8°; 5/5/42—T. 103.8°; 17/5/42—T. 105°; 26/6/42—T. 101.6°. On each of these occasions spironema was found and on each 0.6 g. novostab was administered intravenously while he was pyrexial. *Clinical features*:—Severe headache. For the last six weeks of illness, apart from the acute relapses, he ran a low continuous fever (maximum 100.8° on one day) Showed icteric tinge. Eye examination, 10/4/42: nothing abnormal. *Laboratory findings*:—Thick blood films, 24/3/42, 16/4/42, 5/5/42, 17/5/42, 26/6/42: spironema seen on each occasion. Cerebrospinal fluid, 25/3/42: clear fluid, not under pressure; cells, 15 per c.mm.; protein not increased; chlorides (as NaCl), 730 mg. per 100 c.cm. Venous blood, 25/3/42 and 16/4/42: Kahn-negative. Urine, 18/5/42: Much urobilin present.

Case 2.—Unit A; slept in Cave A on 6/3/42. No knowledge of insect-bites. Reported sick on 15/3/42, suffering from headaches, backache, and shivering attacks. Admitted to hospital on 24/3/42; T. 97°. No lice in clothing, but marks of insect-bites on legs. No spironema found in blood film. On 26/3/42 temperature rose to 99° and *Spironema recurrentis* found in blood film. No fever again until 1/4/42, when temperature suddenly rose to 101.8°, and 0.6 g. novostab was administered intravenously. Was in hospital 14 days. No relapse. *Clinical features*:—Headache, backache, shivering; eye examination on 10/4/42: nothing abnormal. *Laboratory findings*:—Thick blood film, 26/3/42: *Spironema recurrentis* seen. Cerebrospinal fluid, 26/3/42: clear fluid, not under pressure; cells, 5 lymphocytes per c.mm.; protein not increased; chlorides (as NaCl), 720 mg. per 100 c.cm. Venous blood, 26/3/42: Kahn-negative. Urine not examined for urobilin.

Case 3.—Unit A; slept in Cave A on 7/3/42. Bitten by insects while sleeping, just below left eye, which was swollen next day (bite mark visible on admission to hospital). Reported sick 15/3/42, complaining of pains in limbs, shivering, and sweating. Admitted to hospital 24/3/42. Temperature on admission, 103.2°. No lice in clothing. Spironema found in blood film on 24/3/42. Specimens of blood and C.S.F. drawn on 26/3/42 and 0.6 g. of novostab given intravenously. He was in hospital 22 days and had no relapse. *Clinical features*:—Headache, shivering; no nerve palsies. Patient recovered rapidly. Temperature subnormal, and patient allowed up 3 days after admission. Eye examination, 15/4/42: Choroiditis. *Laboratory findings*:—Thick blood film, 24/3/42: Spironema seen. Cerebrospinal fluid, 26/3/42: clear, not under pressure. Cells, 7 per c.mm. (lymphs); protein not increased; chlorides (as NaCl), 680 mg. per 100 c.cm. Venous blood, 26/3/42 and 10/4/42: Kahn-negative. Urine not examined for urobilin.

Case 4.—Unit B; slept in Dungeon B on 4/3/42. No knowledge of insect-bites. Reported sick on 6/3/42; feeling of general malaise and shivering. Admitted to hospital on 8/3/42; temperature 101.9°. No lice on clothing and no marks of insect-bites on body. Apyrexial till 14/3/42, when temperature rose to 103.2°. No spironema seen in thick blood film. Apyrexial again till 17/3/42, when temperature rose to 101°. Spironema was seen in thick blood film; 0.6 g. of novostab administered intravenously while pyrexial. Apyrexial from 19/3/42 to 10/4/42, when temperature rose to 101.8°. Blood film: Spironema seen. Lumbar puncture, and 0.6 g. of novostab given intravenously. Temperature 102° on 11/4/42; normal on 12/4/42, and remained normal till 23/4/42, when patient was discharged from hospital. *Clinical features*:—Severe headaches; eyes not examined. *Laboratory findings*:—Thick blood film, 17/3/42 and 10/4/42: Spironema seen. Cerebrospinal fluid, 10/4/42: clear, not under pressure; cells, 300 per c.mm.; protein not increased; chlorides (as NaCl), 700 mg. per 100 c.cm. Venous blood—Kahn-negative. Urine not examined for urobilin.

Case 5.—Unit B; on guard in Dungeon B on 4/3/42. No knowledge of insect-bites. Reported sick 8/3/42. Admitted hospital 8/3/42; temperature 103.4°. No lice on clothing; no insect-bites on skin; no spironema seen in film. Next day temperature normal, and was apyrexial until 15/3/42, when temperature rose to 102°. No spironema seen in film. Next day temperature rose to 105°; spironema seen in film and 0.6 g. of novostab given on 17/3/42, when temperature was 105.4°. On the following day temperature 98° and remained subnormal till 14/4/42, when he was discharged from hospital fit for duty. *Clinical features*:—Severe headaches which persisted for about 1 week after treatment. Eye examination 10/4/42: nothing abnormal. *Laboratory findings*:—Thick drop blood films, 8/3/42 and 15/3/42, no spironema seen; 16/3/42, spironema seen. Cerebrospinal fluid not examined. Venous blood not examined. Urine not examined for urobilin.

Case 6.—Unit B; on guard, probably in Dungeon B. No knowledge of insect-bites; but it was extremely difficult to obtain a history from this patient. Admitted to hospital 14/1/42 with headache and fever. No lice in clothing or signs of insect-bites. Spironema found in blood film on 14/1/42, and 0.45 g. of novostab given while pyrexial. Next day was apyrexial, and remained so until discharge from hospital on 31/1/42. Readmitted to another hospital with fever on 8/2/42. Blood film sent to laboratory here on 12/2/42; spironema found. In hospital until 27/2/42, during which time he received 3 injections of novostab. Readmitted to this hospital on 10/3/42; temperature 105°. Spironema found in blood film on 11/3/42, and 0.6 g. sulphostab given intravenously while pyrexial. He was discharged from hospital on 17/4/42, and had no subsequent relapse when seen on 5/7/42. *Clinical features*:—Headache, fever. Eye examination, 10/4/42: Fundus right disk rather pale; edges very hazy, and physiological cup filled in. Fundus left disk better colour; edges more distinct, not quite normal. Conclusion—slight papillitis. *Laboratory findings*:—Thick blood films, 14/1/42, 12/2/42, and 11/3/42: Spironema seen. Cerebrospinal fluid, 17/1/42: Clear fluid, not under pressure; cells less than 5 per c.mm.; protein not increased; chlorides (as NaCl), 680 mg. per 100 c.cm. Venous blood, 17/1/42: Kahn-negative. Urine not examined for urobilin.

Case 7.—Unit C; slept in Cave C in March; no knowledge of insect-bites. Reported sick 10/5/42 with headache and fever. No lice on clothing, no marks of insect-bites. Admitted to hospital on 11/5/42; temperature rose to 100.8° and was subnormal next day, remaining subnormal till 17/5/42, when it suddenly went up to 102.6°. Blood film: No spironema seen. Temperature again normal on 18/5/42, and remained normal till 23/5/42, when it rose to 101.8°, and on 24/5/42, when it rose to 102.4°. On this latter date spironema was found in blood film, and 0.6 g. novostab was given intravenously while he was pyrexial. Temperature next day was 97° and remained subnormal till 27/5/42, when it rose to 99.2°. Apyrexial till 7/6/42, when he was discharged. *Clinical features*:—Shivering attacks, headaches, dizzy turns. Eyes not examined. *Laboratory findings*:—Thick blood films, 17/5/42 and 23/5/42, no spironema seen; 24/5/42, spironema seen. Cerebrospinal fluid not examined. Venous blood, 24/5/42: Kahn-negative. Urine, 24/5/42: urobilin present.

Case 8.—Unit D; worked beside Cave D. No knowledge of insect-bites. Admitted to hospital 10/8/42; temperature 101°. No spironema found in blood film. On 11/8/42 temperature normal. On 12/8/42 temperature 101°, and spironema found in blood film. Temperature next day normal, and remained apyrexial till 18/8/42, when it rose to 98.9°; temperature normal next day and remained so until 6/9/42, when it rose to 99.6°. Temperature normal the following day. During this time he felt ill and complained of headache and nausea, so, although apyrexial, 0.6 g. of sulphostab was given intravenously on 13/9/42. Had no recurrence of pyrexia, and was discharged fit on 19/9/42. *Clinical features* :—Sulphostab was withheld, as it was hoped he would develop pyrexia. However, temperature did not surpass 99.6° at this time, but patient looked ill and complained of headache and nausea. Eventually, after having sulphostab, his general condition and appetite improved and headaches disappeared; he was discharged fit six days later. Eye examination on 18/9/42: Edges of both disks hazy; disks slightly swollen about 2D. No haemorrhage in retina, but not good colour. Conclusion: Bilateral papillitis. *Laboratory findings* :—Thick blood films, 10/8/42, no spironema seen; 12/8/42, spironema seen. Cerebrospinal fluid, 7/9/42: Clear—not under pressure; cells less than 5 per c.mm.; protein not increased; chlorides (as NaCl), 700 mg. per 100 c.cm. Venous blood, 12/8/42: Kahn-negative. Urine, 12/8/42: Much urobilin present—much urobilinogen.

---

* The spironema transmitted by *O. tholozani* is described as *S. persica*.

Case 9.—Unit D; has worked in vicinity of Caves A and D. Slept in the open on several occasions while on manœuvres. No history of being bitten while sleeping in open. Admitted to hospital 10/8/42; temperature normal. No lice in clothing and no marks of insect-bites on body. Temperature rose to 102° on day of admission. Spironema seen in thick blood film; 0.6 g. of sulphostab given intravenously while pyrexial. Next evening the temperature was normal and remained normal until 19/8/42, when it suddenly rose to 102.4°. Thick blood film: No spironema seen; 0.6 g. of sulphostab given intravenously while pyrexial. Temperature normal next day and until 10/9/42, when he was discharged fit for duty. *Clinical findings* :—Pain in lumbar region, attacks of dizziness. Aching behind eyes and unable to focus clearly on print even when apyrexial. Eye examination on 5/10/42: Slight papillitis left disk. *Laboratory findings* :—Thick blood films, 10/8/42, spironema seen; 19/8/42, no spironema seen. Cerebrospinal fluid not examined. Venous blood, 10/8/42: Kahn-negative. Urine, 10/8/42: no urobilin.

Case 10.—Unit E; dug trench near Cave E. Admitted to hospital 10/8/42 complaining of headache and shivering. Temperature 103.8°. No lice on clothing or evidence of insect-bites on body. Spironema found in thick blood film on 10/8/42; 0.6 g. of sulphostab was given intravenously. Next day temperature normal, and remained normal until 25/8/42, when he was discharged from hospital. Admitted to another hospital complaining of headache and general malaise. Ran a low fever, and was transferred to this hospital on 31/8/42. Continued to run a low fever until 11/9/42, when he had a rigor and temperature rose to 101.8° and 0.6 g. sulphostab was given intravenously. Temperature fell to normal 13/9/42, and remained so. *Clinical features*:—Headache, eyeache, unable to read much because of aching behind eyes. Ran a low fever for 3 weeks. Eye examination: On 7/9/42, slight papillitis about 2D both disks; 21/9/42, left disk slightly more swollen than on 7/9/42. *Laboratory findings* :—Thick blood film, 10/8/42, spironema seen. Cerebrospinal fluid: Clear fluid not under pressure; cells, 20 per c.mm. (lymphocytes); protein not increased; chlorides (as NaCl), 740 mg. per 100 c.cm. Venous blood, 10/8/42 and 24/8/42: Kahn-negative. Urine: 10/8/42, much urobilin present: 3/10/42, urobilin present.

Case 11.—Unit F; slept in Cave F 28/9/42. No knowledge of insect-bites. Reported sick on 8/10/42, suffering from pains in head, back, and shoulders, and one severe attack of shivering. Admitted to hospital 8/10/42; temperature 103.2°. No lice on clothing or marks of insect-bites. Spironema found in blood film on day of admission. Was given 0.6 g. sulphostab intravenously while pyrexial; in 36 hours was apyrexial, and has remained so for 28 days. *Clinical features* :—Herpes of lips, headache, backache. Eye examination: Slight degree of papillitis. *Laboratory findings* :—Thick blood film, 8/10/42: Spironema seen (also seen by dark-ground examination). Cerebrospinal fluid, 11/10/42: Clear fluid not under pressure; cells less than 5 per c.mm.; protein not increased; chlorides (as NaCl), 727 mg. per 100 c.cm.; sugar, 90 mg. per 100 c.cm. Venous blood, 8/10/42: Kahn-negative. Urine, 8/10/42: much urobilin present.

Case 12.—Unit F; slept in Cave F 28/9/42. Insect-bites on left arm. Reported sick on 10/10/42 with fever. He was detained in the local M.I. Room and treated for sandfly fever. He was apyrexial on 12/10/42 and returned to duty. Admitted to hospital on 20/10/42; temperature 103.6°. No lice on clothing or marks of insect-bites. Spironema found in blood on day of admission; 0.6 g. of sulphostab was given intravenously while pyrexial. Next day was apyrexial, and has remained so for 14 days. *Clinical features*:—Headache, shivering—probably admitted to hospital during the first relapse, having been infected on the same night as Case 11. Eye examination on 24/10/42: Nothing abnormal. *Laboratory findings* :—Thick blood film, 20/10/42, very numerous spironema seen—also seen by dark-ground examination. Cerebrospinal fluid, 21/10/42: clear fluid, not under pressure; cells 4 per c.mm. (lymphocytes); protein not increased. Chlorides (as NaCl), 755 mg. per 100 c.cm. Venous blood, 20/10/42: Kahn-negative. Urine, 20/10/42: urobilin present in large amounts.

Summary and Conclusions

Ornithodorus tholozani has been found in caves in Cyprus. Soldiers sleeping in these caves have contracted relapsing fever. As this tick is a known vector of relapsing fever in other parts of the Levant it may be concluded that tick-borne relapsing fever also occurs in Cyprus. Twelve cases are described.

The incubation period of the disease varies. While usually lasting from 8 to 10 days, it appears likely that in some cases it can be as short as 2 days or as long as 5 weeks.

In 2 cases long periods of low continuous fever occurred as well as acute attacks of high pyrexia.

All cases were treated by intravenous arsenicals while pyrexial. Five of these relapsed in spite of treatment, but only two relapsed more than once.

Choroiditis was observed in one case, papillitis in 4 other cases. No other neurological complications could be discovered except for changes in the cerebrospinal fluid.

The cerebrospinal fluid in 4 cases showed a lymphocytic pleocytosis. In one case 300 cells per c.mm. were observed. In 2 cases the chloride concentration in the cerebrospinal fluid was reduced to 680 mg. per 100 c.cm.

All cases in this short series gave negative Kahn reactions.

In 7 cases the urine was examined for urobilin by Schlesinger's test. Marked urobilinuria* was observed in 6.

[More recently, one of us, K. C. D., has succeeded in infecting guinea-pigs with blood from a further case of relapsing fever contracted in Cyprus. This substantiates the view that the disease is tick-borne, since the louse-borne type is not transmissible to guinea-pigs, and that the spirochaete is *S. hispanica*, not *persica* as previously considered.]

We are very grateful to Major J. Clark, R.A.M.C., for his kind co-operation in searching the caves and for forwarding the ticks for identification; to Dr. J. G. Shelley for his careful ophthalmological examinations; and to Capt. B. T. Broadbent for photographing the specimen. We wish to thank Col. J. S. K. Boyd for his kind interest in this work.

PROPHYLAXIS OF PARALYTIC ILEUS BY ADMINISTRATION OF MORPHINE

BY

J. T. CHESTERMAN, M.R.C.P., F.R.C.S., F.A.C.S.
Surgeon, City General Hospital, Sheffield

AND

W. J. SHEEHAN, B.A., M.B., Ch.B., B.A.O.
Assistant Obstetrician, City General Hospital, Sheffield

The clinical impression has been formed in the last few years that morphine is of value in the prophylaxis of "paralytic ileus." We are unaware of any previous statistical evidence for this belief, but we regard the following analysis as of value, because the treatment was altered from a non-morphine to a morphine routine with the specific object of lessening its post-operative incidence. The accepted definition of post-operative "paralytic ileus" is the failure to pass flatus within 60 hours at the end of an operation, and Caesarean section, owing to the laxity of the abdominal wall and haemoperitoneum, is recognized as predisposing to this condition.

The data submitted for analysis consist of particulars relating to 500 consecutive patients upon whom Caesarean section was performed when under the care of Dr. W. J. Clancy in the City General Hospital, Sheffield. In the pre-morphine period the drug was given only when necessary to relieve pain, while in the second period the routine was as follows: Morphine gr. 1/4 was given 6-hourly for the first 24 hours (if the patient was asleep the injection was given on awaking, and so on 6-hourly). If distension was present the morphine was continued in the same way for a second period of 24 hours. In any case morphine gr. 1/4 was given at night for the first four nights. Fluids were limited to 3 pints a day until flatus was passed, after which the diet was rapidly increased to normal.

There were 160 Caesarean sections before the morphine routine was introduced, with 8 cases of ileus, and in the second period there were 340 Caesarean sections, with 3 cases of ileus, thus giving rates of 5% in the pre-morphine period as compared with 0.88% in the morphine period a difference of 4.12 ± 1.40, which is greater than could easily be ascribed to chance. The statistical problem, therefore, is whether it may be validly deduced that the lower rate could have resulted from the institution of morphine therapy.

---

* This appears to be a general occurrence in relapsing fever, and is being described elsewhere.

The criterion of statistical significance adopted throughout the analysis is that any difference to be real—i.e., unlikely to have occurred from the play of chance—must exceed twice its standard error. It is unlikely that such will occur by chance more than five times in a hundred trials.

TABLE I.—*Annual Number of Births, Caesarean Sections, and the Occurrence of Ileus in the Two Periods*

	Births	Caesareans	Paralytic Ileus	Caesareans as % of Births	Ileus as % of Caesareans
Non-morphine period:					
1935	1,027	21	0	2·04	0
1936	1,186	22	1	1·85	4·5
1937	1,276	39	1	3·06	2·6
1938	1,219	46	4	3·77	8·7
1939 (to Aug.) ..	1,003	32	2	3·19	6·3
Total	5,711	160	8	2·80	5·0
Morphine period:					
1939 (Sept. to end)	519	11	0	2·12	0
1940	1,549	37	0	2·39	0
1941	1,066	55	1	5·16	1·8
1942	1,304	46	1	3·53	2·2
1943	1,568	76	1	4·85	1·3
1944	1,936	73	0	3·77	0
1945 (to July 1) ..	919	42	0	4·57	0
Total	8,861	340	3	3·84	0·88

It may be noted that the number of births in the second period is 50% higher than in the first, but this is hardly relevant to the problem, and it also should be noted that the proportion of Caesarean sections to births has increased from 2.80 to 3.84% (difference 1.04±0.31%)—outside the probability of chance, owing to the increasing percentage of complicated cases admitted.

The following information was supplied with regard to each case: (1) Date of operation and hospital number. (2) Age of patient. (3) Parity. (4) Type of operation—classical, repeat classical, lower segment, repeat lower segment. (Some slight errors may be involved here, as cases of repeat section were labelled according to the time under discussion, for in some instances it was impossible to ascertain which operation had been performed previously.) (5) Indication—mechanical, haemorrhage, toxic, or cardiac.

TABLE II.—*Age Distribution*

	Under 25	25—	30—	35—	40+	Total
Pre-morphine ..	46	52	43	17	2	160
Morphine ..	43	77	82	94	44	340
Total ..	89	129	125	111	46	500

$\chi^2 = 50{\cdot}5$. $n' = 4$. $P < 0{\cdot}01$.

It is clear that the age groups are not similar, there being an excess of patients over 35 in the second group, which is not readily accountable to chance and is undoubtedly due to the increased age of confinement found after the conscription of women.

TABLE III.—*Parity*

	1	2	3	4+	Total
Pre-morphine	99 (4)	40 (3)	10	11 (1)	160
Morphine	172 (1)	101 (1)	25 (1)	42	340
Total ..	271 (5)	141 (4)	35 (1)	53 (1)	500

$\chi^2 = 6{\cdot}99$. $n' = 3$. $P > 0{\cdot}05 < 0{\cdot}10$.

No difference greater than could be ascribed to chance is found between the two series as regards parity. The figures in parenthesis indicate the distribution of ileus cases, and it seems clear that parity may be exonerated as a factor relevant to ileus.

TABLE IV.—*Type of Operation*

	Classical	Repeat Classical	Lower Segment	Repeat Lower Segment	Total
Pre-morphine ..	67 (3)	28 (1)	62 (4)	3	160
Morphine ..	131 (1)	59 (1)	134 (1)	16	340
Total ..	198 (4)	87 (2)	196 (5)	19	500

$\chi^2 = 2{\cdot}53$. $n' = 3$. $P > 0{\cdot}30 < 0{\cdot}50$.

Here again the distribution of the two series by type of section is not dissimilar, nor does paralytic ileus (figures in parenthesis) seem to be particularly associated with any one type.

TABLE V.—*Indication*

	Mechanical	Haemorrhage	Toxic or Cardiac	Total
Pre-morphine ..	148	10	2	160
Morphine ..	270	49	21	340
Total ..	418	59	23	500

$\chi^2 = 14{\cdot}2$. $n' = 2$. $P < 0{\cdot}01$.

In the morphine period the indication was other than mechanical to a greater degree than in the pre-morphine period, this in all probability being due to the increased age of the group.

The tabulations above suggested that both age and indications warranted more detailed analysis, as follows:

TABLE VI

Indication	Age					
	Under 25	25—	30—	35—	40+	Total
	Pre-morphine period					
Mechanical ..	46 (3)	47 (2)	40 (2)	13	2	148
Haemorrhage ..		5	2	3		10
Toxic			1	1 (1)		2
Total ..	46 (3)	52 (2)	43 (2)	17 (1)	2	160
	Morphine period					
Mechanical ..	33	65	69 (1)	72 (2)	31	270
Haemorrhage ..	8	9	11	14	7	49
Toxic	2	1	1	8	6	18
Cardiac		2	1			3
Total ..	43	77	82 (1)	94 (2)	44	340

It will be seen that with one exception all the cases of "paralytic ileus" (figures in parenthesis) occurred where the indication was mechanical. But even among these cases the incidence of ileus was lowered in the morphine period from 4.7 to 1.1% (difference 3.6 ± 1.56, which is significant).

The difference in age of the two groups can also be said to have little to do with the results, though here the numbers are too small for statistical proof. In the second, or morphine, series the ileus cases occurred in the older age groups, while in the earlier series they occurred in the younger groups.

Using two age groups only, then on the basis of the ileus rates experienced among the mechanical indications in the pre-morphine period we should expect (as shown in Table VII) 11.6 cases to occur in the morphine period. Actually only 3 occurred.

TABLE VII.—*Mechanical Indications Only*

Age Group	Pre-morphine			Morphine		
	Caesareans	Ileus	Rate	Caesareans	Expected Ileus	Actual
Under 30 ..	93	5	5·37	98	5·3	0
30+ ..	55	2	3·64	172	6·3	3
					11·6	3

$$\frac{\text{Difference}}{\sqrt{\text{Expected}}} = \frac{8{\cdot}6}{3{\cdot}4} = 2{\cdot}52$$

Taking the square root of the expected number as an approximation to the standard error of the difference, the ratio of the difference to its standard error exceeds 2, and the decrease in the second period may therefore be regarded as a real one.

Discussion

The objective of the analysis was to ascertain whether or not the two series of patients were similar in all respects except as regards treatment and to make allowances for differences which might be found. The results show similarity in regard to parity and type of operation, but dissimilarity in regard to age and indication. While the conclusion must be that the "paralytic ileus" rate was lowered after morphine therapy started, the statistical analysis can only be claimed to show that the decrease was greater than could easily be ascribed to chance and that it was not due to inherent differences in the two series as regards age, parity, and type of operation or indication.

Conclusion

The essential difference between the two series of cases from the clinical point of view is the introduction of a morphine routine in the second group, and we feel that the results (5% paralytic ileus as against 0.88%) are attributable to this factor, as the two series are as near parallel as can be expected in 500 consecutive Caesarean sections.

We wish to express our indebtedness and thanks to Dr. E. Lewis-Faning, of the Medical Research Council's Statistical Staff, for the statistical analysis and comments, without which this paper could not have been written. We also thank Dr. W. J. Clancy for his help and co-operation in this subject for some years past, and Dr. J. Rennie and Dr. J. Clark for permission to publish this article.

ACID-FAST ORGANISMS IN GASTRIC RESTING JUICE

BY

JOHN YATES, M.B., B.S.

Formerly Demonstrator of Pathology and Bacteriology, Guy's Hospital Medical School

This investigation was undertaken after a physician had remarked that he occasionally had acid-fast organisms reported in the gastric juice of patients when he was certain that the tubercle bacillus was not present in the patient's sputum.

The Investigation

Technique.—The specimens of gastric resting juice were obtained from out-patients attending Guy's Hospital for fractional test meals. None of them were known or suspected to be suffering from tuberculosis. Each specimen was treated with antiformin, and smears were made and stained by the Ziehl-Neelsen method, decolorization being carried out with both 25% sulphuric acid and 90% alcohol. The smears were each subjected to a ten-minute microscopical search for acid-fast bacilli. When these were found the neutralized and washed centrifugalized deposit was planted on Loewenstein's medium and incubated at 37° C. for at least six weeks, and a portion of the deposit was also injected into a guinea-pig.

Findings.—171 specimens were examined. In seven of them acid-fast organisms were seen. None of the seven showed more than two or three such organisms per slide in a prolonged search. They were mostly of a short and stout shape, unlike true tubercle bacilli, and often had a ragged deformed appearance. On culture three of the seven specimens gave a growth of saprophytic acid-fast organisms which grew equally well at room temperature and failed to produce tuberculous lesions in a guinea-pig. All seven specimens on guinea-pig inoculation had failed to produce any lesions when the animal was killed seven weeks later. The fractional test meal carried out on these seven cases at the same time that the resting juice was obtained showed in two cases hyperchlorhydria, in one case hypochlorhydria, and the remaining four gave a normal result. Control investigations carried out on three patients suffering from open tuberculosis (two children and one adult) showed typical tubercle bacilli present in large or moderate numbers in the resting juice.

Conclusion

In 4.6% of resting-juice specimens examined acid-fast organisms were present. These organisms were also alcohol-fast. As pointed out by Van Diense and Hooghiemster (1938) alcohol resistance of an acid-fast organism is not sufficient to identify it conclusively as the tubercle bacillus. In this case they proved to be saprophytes, ingested very possibly with fruit and vegetables, on which they are commonly found.

It appears, from the cases investigated, that under normal conditions the chance of tubercle bacilli being found in the gastric resting juice of non-tuberculous patients is very remote.

Since the examination of gastric washings for the tubercle bacillus is a valuable diagnostic proceeding it should be noted that mere films where acid-fast bacilli are few and possibly deformed in appearance may perhaps be misleading without further investigation.

MASSIVE SURGICAL EMPHYSEMA, PNEUMOTHORAX, AND PNEUMOPERITONEUM

BY

RONALD JONES, M.D., M.R.C.P.

Honorary Physician, East Suffolk and Ipswich Hospital

Massive surgical emphysema developing suddenly during or after intubation of the tracheo-bronchial tract raises problems, including those of prevention and treatment, as shown in the cases described herewith.

Case I

A married woman aged 58 was admitted to hospital on Aug. 15, 1944, for bronchoscopy, as bronchial growth had been suspected. Premedication was by morphine 1/6 gr. and atropine 1/100 gr. General anaesthesia was induced by pentothal. The bronchoscopic examination (Aug. 18) was conducted uneventfully by Mr. K. W. Mackenzie, and no abnormality was found. A few moments after the bronchoscope had been removed the right eyelid was noted to be swollen. Very quickly this swelling spread to the face and neck. She became deeply cyanosed and respiration ceased. A needle was inserted into the anterior mediastinum above the suprasternal notch, but no air escaped. A laryngoscope was introduced into the throat, and the pharynx was found to be occluded by swollen spongy mucous membrane. The bronchoscope was then reintroduced, with difficulty. The trachea was found to be occluded by grossly swollen mucous membrane. After further manipulation the bronchoscope was introduced as far as the bifurcation of the trachea. The right main bronchus was occluded, but there was a very small passage in the much-swollen left bronchus, and oxygen was directed into it through the bronchoscope and artificial respiration started. By now she was pulseless and extremely cyanosed. At this stage the abdomen was noted to be grossly distended and tympanitic. Two needles were introduced into the flanks and air at once hissed out. Artificial respiration was continued and the pulse quickly returned, followed by spontaneous respiration and improvement of colour, the disappearance of the bronchial swelling being seen to occur during the next ten minutes. She was returned to the ward 1½ hours later, and recovered consciousness about four hours after leaving the theatre. She was given 51 g. of sulphamezathine between Aug. 19 and 25 to prevent mediastinitis. During this period the temperature remained between 97° and 100.8°. A radiograph of the chest and abdomen on Aug. 19 showed a right-sided pneumothorax and a considerable pneumoperitoneum. A further radiograph on Aug. 29 showed neither pneumothorax nor pneumoperitoneum. She was discharged on Aug. 31 symptomless, apyrexial, and free of physical signs, and has remained well since.

No oxygen was administered to this patient until after the emphysema had developed, and it can only be surmised that the laryngeal, tracheal, or bronchial mucosa was damaged by the bronchoscope. It is not easy to account for the pneumoperitoneum, but the presumption is that air in the mediastinum forced its way through one or other of the weakly protected orifices in the diaphragm into the retroperitoneal space. There is no anatomical route to explain its passage from the retroperitoneal space into the peritoneal cavity. Rupture of the peritoneum by adhesions due to distension of the retroperitoneal space would be a possible explanation. The same difficulty arises in explaining the pneumothorax.

The speedy recognition and treatment of the obstructed airway and of the pneumoperitoneum undoubtedly saved the life of this moribund patient.

Case II

A boy aged 5½ was admitted to hospital for bronchography under general anaesthesia. Acute mediastinal emphysema and a bilateral shallow pneumothorax occurred as a result of a sudden delivery of oxygen into an intratracheal catheter, the accident being due to a faulty check-valve. Acute emphysema quickly developed, beginning with the eyelids and rapidly involving the face, neck, and upper chest. Needles were inserted into the neck, and the superior mediastinum was entered; no air could be aspirated. The left chest seemed hyperresonant, but no air escaped from a needle inserted into it. Oxygen was given by the B.L.B. mask, and the child made a complete and uneventful recovery. He was discharged five days after bronchography, the radiograph taken on discharge showing that both lungs had completely re-expanded.

Conclusions

Prevention.—While it is not always possible to prevent this condition, as in Case I, there are certain important rules to be observed: (*a*) maintenance of a free airway; (*b*) avoidance of high intra-alveolar pressures—e.g., due to sudden rush of oxygen or anaesthetic gases or to the patient straining; (*c*) care in manipulating tubes so as to avoid damaging the respiratory tract mucosa.

Treatment.—Attention to the following points in treatment, with the possible exception of (*c*), has been an important factor in saving the lives of patients: (*a*) Aspiration of the ballooned tissues of the neck should be attempted, as described by Barrett and Dillwyn Thomas (1944). (*b*) Obstruction of the airway should be relieved; pure oxygen should be administered under low pressure. (*c*) Signs of pneumothorax should be sought and, if present, pleural puncture should be carried out. (*d*) The abdomen should be examined and needled if gross tympanitic distension is present.

I am indebted to Mr. K. W. Mackenzie and Prof. H. A. Harris for their help and criticism.

A NOTE ON FAT EMBOLISM

BY

H. J. NIGHTINGALE, M.S.Lond., F.R.C.S.

Senior Honorary Surgeon, Royal South Hants and Southampton Hospital

Fat embolism enjoys a curiously honoured place in surgical literature, for no very obvious reason. Everyone knows of it because the most elementary textbook intended for the beginner invariably devotes valuable space to it; but how many surgeons have consciously seen a case and recognized it? The great similarity of all the accounts in the textbooks, large and small, suggests that the writers themselves have had no practical experience of the subject, and that, like their readers, they have gained their information from books. What makes this more extraordinary is that the British surgeon has written so little about it. When Watson (1937) wrote a full account of a case he appended a copious bibliography of some 50 items, in which the only paper from a British source was one dated 1882. Since then Robb-Smith (1941) has dealt fully with the condition from a pathological standpoint, Rowlands and Wakeley (1941) have recorded three cases, and Wilson and Salisbury (1944) eight cases in 1,000 battle casualties.

Put briefly, it may be said that fat embolism of the lungs is probably much more common than is recognized, though embolism in the systemic circulation is very rare. Robb-Smith thought that, of a series of 125 cases of death from accident, in 29 fat embolism probably played a major part in producing a fatal result; but both the symptoms and the post-mortem picture so closely resemble those found in bronchopneumonia that unless special staining technique is employed, such as he describes, the true nature of the condition will be missed.

The difficulty in systemic embolism is to explain how the fat passes through the lung capillaries in a globule large enough to cause trouble elsewhere. Possibly minute globules which can pass through the lungs coalesce into larger ones on reaching the heart and being subjected to the churning movements of that organ. This would appear to be more probable than the ingenious, if fantastic, suggestion of one writer that this condition can occur only in a patient with a patent foramen ovale.

The case now under consideration is a little unusual in that there were no pulmonary signs at all. The usual course of events is that after a fracture there is a period of 24 hours when the patient is comfortable, and then, somewhat suddenly, he becomes dyspnoeic and cyanosed and sweats profusely. Sputum is scanty and frothy, and may, but only rarely, have fat in it. Later he may show delirium, strongly resembling delirium tremens. By this time the surgeon has probably most unfairly blamed the anaesthetist on the one hand and the patient's habits on the other. The anaesthetist, if he knows the literature, will retaliate with an accusation of rough manipulation—again perhaps unjustly, as the case described below had neither manipulation nor anaesthetic.

Case History

A man aged 59 sustained a fracture of the left tibia and fibula, with some displacement, on March 21, at 12.30 p.m. He was transferred from one hospital to another owing to shortage of beds and was admitted, quite comfortable, in box splints. At 6.30 that evening, before he could be put up in plaster, he suddenly collapsed, with faintness, cold and clammy skin, and a pulse rate of 56. There was no dyspnoea or cyanosis. During the night he was wandering and strange in manner, and the next morning he was comatose. The limbs were a little spastic, the knee- and elbow-jerks were exaggerated, and the plantar reflexes extensor; abdominal reflexes were absent. Pupils were equal but very small. Petechial haemorrhages were present in the skin. Lumbar puncture produced a clear fluid under normal pressure: cells, 2 per c.mm., all small lymphocytes; protein, 0.04%; no globulin. His condition rapidly deteriorated, the temperature rising steadily to 104°, and death occurring 72 hours after admission

At the necropsy only the brain was examined, and that showed the typical picture of multiple pin-point haemorrhages scattered through the white matter only. The excellent coloured photograph in Watson's article might have been taken from this case. I am indebted to Dr. H. H. Gleave for the report on the pathological specimen:

"*Brain.—Macroscopic*:—The cerebrum shows numerous tiny points of haemorrhage scattered in the white matter. The grey matter is not affected. *Microscopic*:—The small vessels of the white matter show perivascular haemorrhage and necrosis. These changes occur without any evident relation to a vessel. No change is seen in the cortex. Frozen sections stained for fat show globules and masses of fat in some of the vessels. No fat can be demonstrated in the majority of the vessels, but where it is present the appearance is characteristic. There is no inflammatory reaction around the necrosed area."

This follows closely the descriptions given in the other articles already quoted. The interesting point is that, although quite definite fat emboli can be seen in the vessels, they are neither so numerous nor so striking as the areas of necrosis and haemorrhage.

Comment

The symptoms in this case appear to be quite typical. Briefly, the important points to look for, as shown by this and other cases, are:

1. A latent period of three hours to three days.

2. A sudden collapse associated with profuse sweating and cyanosis, but no fall of blood pressure. As one American writer puts it pithily: "Shock—three hours. Fat embolism—three days. Pulmonary embolism—three weeks." This collapse and the very profuse sweating which has been referred to by all observers should help to distinguish this condition from pulmonary oedema or bronchopneumonia.

3. Pin-point pupils, exaggerated deep reflexes with absent abdominal reflexes but no localizing signs. Cerebrospinal fluid normal.

4. Hyperpyrexia in the later stages. Petechial haemorrhages make the diagnosis certain. Fat may occasionally be found in the sputum or urine, but not often enough to be of much help.

Medical Memoranda

Staphylococcus pyogenes Septicaemia treated with Penicillin

The report of Howells *et al.* (1945) on the successful use of penicillin in two cases of *Staph. pyogenes* septicaemia prompts me to hope that the following case might also be worthy of record.

Case Report

A Polish officer aged 53 was admitted to the Royal Masonic Hospital on April 27, 1945, complaining of continuous epigastric pain during the past four weeks. He gave a history of trichiniasis at the age of 15 and rheumatic fever at 25. In 1940, at a routine medical examination, evidence of organic heart disease was discovered, and he was down-graded to the lowest category. Apart from occasional palpitation and indefinite fleeting pains in various parts of his body, he remained in reasonably good health until one month before admission, when he gradually became aware of increasing upper abdominal pain, unaffected by food. Two weeks later the pain became much more severe, so that he was unable to sleep. He was treated for indigestion, but without result. For the three days preceding his admission to hospital he had observed oliguria. He had no cough, dyspnoea, or chest pain, and had lost no weight.

On examination he did not seem to be very ill. His temperature was 100.6° F., pulse 100, and respirations 20 a minute. There was slight cardiac enlargement to the left, the aortic and pulmonary second sounds were about equal in loudness, and there was a rough systolic apical murmur transmitted towards the axilla. No thrill was palpable. The rhythm was regular, the B.P. 150/95. The lungs were clear; the abdomen was distended and tympanitic; the liver was not obviously enlarged, but its edge was tender on deep inspiration; the spleen was not palpable. There was minimal oedema of the ankles. No other abnormalities were detected. Blood count: leucocytes, 9,000 per c.mm. (neutrophils 7,290, eosinophils 270, basophils 0, lymphocytes 1,170, and monocytes 270 per c.mm.). Blood urea, 43 mg. per 100 c.cm. Urinalysis: albumin, faint trace; occasional leucocyte, erythrocyte, and granular cast. Chest skiagrams showed some prominence of the aortic arch, but nothing else abnormal. E.C.G. within normal limits.

The patient continued to run a low-grade intermittent pyrexia with an evening rise of temperature to 100–101° F., and there was little change in his general condition until May 2, when, during the night, he complained of considerable abdominal pain, chiefly in the left hypochondrium. In the morning his spleen could easily be palpated three fingerbreadths below the costal margin; it was slightly tender. Blood cultures were taken, and after five days' incubation *Staph. pyogenes aureus* was grown. The organism was coagulase-negative and its sensitivity to sodium penicillin was greater than the standard Oxford strain. Accordingly, on May 11 a course of intramuscular injections of penicillin, 15,000 Oxford units 3-hourly, was begun. On that evening the temperature rose to 101.2° F., and was 101° F. on the following evening, but thereafter it fell progressively, and from May 16 onwards (the sixth day after starting penicillin therapy) it never exceeded 98.4° F. In all, 2,040,000 units of penicillin were given over a period of 17 days. Within two days of the commencement of penicillin therapy the patient claimed to be feeling much better, and he made an uninterrupted and uneventful recovery, to be discharged in apparently good health, though still with an enlarged, but non-tender spleen, on June 26—29 days after cessation of penicillin therapy. It is interesting to note that during the month of June he sat the London University B.A. final examination in classics, while still a patient in the hospital.

Discussion

At first the diagnosis was obscure, and it was thought that there was a mild degree of cardiac failure, of rheumatic origin, causing abdominal discomfort as a result of portal congestion, but the persistent intermittent pyrexia remained unexplained. The sudden development of splenomegaly accompanied by severe abdominal pain immediately suggested splenic infarction due to subacute bacterial endocarditis and led to the taking of blood cultures. The fact that these grew *Staph. pyogenes aureus*, together with the rapid, satisfactory, and apparently complete cure by means of penicillin, strongly suggests that the disease process was merely a septicaemia, without any actual endocarditis, while the constancy of the cardiac signs—the apical systolic murmur having remained unchanged—still further bears this out. This case, therefore, was one of simple *Staph. pyogenes* septicaemia of obscure origin, successfully treated with penicillin.

Hysteria Mimicking Meningism

The pleomorphism of hysteria should be kept in mind when making a diagnosis of acute cerebral disease, otherwise a bed may be occupied, unnecessary investigations made, and the doctors' time wasted; nor should the fact be forgotten that any investigations or examinations tend to "fix" conversion symptoms as a reality in the patient's mind, making their removal more difficult and the ultimate prognosis worse.

Case History

The medical officer of an R.A.F. station was called at 1.30 o'clock on a Saturday morning to see an airman who had been discovered unconscious at the foot of a ladder in a room which he had been painting; there was no witness of the man's collapse, and the only history available was that he had had a headache of increasing intensity for three days. Physical findings were as follows:

The patient was a young man of good physique, with no signs of injury. He lay on his side, curled up, with his face turned from the light; he showed hyperaesthesia—being resistant to interference, and holding his head, which appeared to be aching severely. Beyond these manifestations he could not be roused. Physical examination otherwise was negative. Pulse 76, temperature 98.5°, respirations 22. He was immediately transferred to an isolation hospital for observation.

When the M.O. was discussing the case with his Service colleague the next morning, the latter was immediately struck by the resemblance of the history to a case that he had seen when working as a psychiatrist at an E.M.S. neurosis centre. The patient's best friend was sent for, and on questioning about the airman's domestic life, etc., revealed that his fiancée had broken off their engagement a week previously. The doctor at the isolation hospital was given this information, with the suggestion that hysteria should be considered as a possible diagnosis, but full investigations were in progress, and the patient had been placed on the "dangerously ill" list. Lumbar puncture and skiagrams of the skull were normal and no physical findings other than those detailed above were elicited at any time. He was being nursed in the dramatic surroundings of a glass-walled isolation ward, and his mother expressed the intention of not leaving his side until he "became conscious." On Monday morning one of us visited him, and he looked ill, having a bloated appearance, his face being purple-hued from lying in one position for a prolonged period. The only reaction that could be elicited was a restlessness when his financée's name was mentioned. On the Wednesday, the fifth day of illness, the patient's condition was unchanged; he had eaten nothing and drunk little. The doctor of the isolation hospital agreed that the case was not infectious and the patient was returned—in the same state as originally found—to the R.A.F. station sick quarters. Immediately on his arrival intravenous pentothal was administered by one of us; the patient abreacted, two main emotional precipitants being evoked—his broken engagement and his distress over the wounding of a brother who was fighting in Burma. The patient made a rapid recovery.

The history of the case that gave the clue on this occasion was briefly as follows. A middle-aged soldier, who had been painting a room alone, was found unconscious at the foot of his ladder in the middle of the night; he was admitted to a Service neurological hospital, where for four months he underwent exhaustive investigations. He was unconscious for three days and then became totally blind. Four trephine holes were made in a search for subdural haematoma. Four months later, when he was admitted to the neurosis centre, the task of the psychiatrist was simple, as all possible organic causes for his blindness had been eliminated. He recovered his sight within a day, after abreaction under sodium amytal, the (apparently) trivial cause of all the trouble being his dislike of Service life and resentment at having to work alone every night for a fortnight without assistance.

Comment

It is not often realized by practitioners that a very trivial situation in the present may act as a precipitant of conversion symptoms of severe or even fatal intensity as, for example, may be seen in anorexia nervosa. The hysterical condition may so dominate the picture as to repress the normal instincts whose satisfaction is necessary for survival. The illogicality of hysterical symptoms is borne out well in the second case mentioned. An apparently trivial stimulus rendered a man unconscious for three days and blind for four months. He had to undergo the discomforts and hazards of several lumbar punctures, a ventriculogram, and a general anaesthetic so that his skull might be trephined.

A. H. Meyer (*Ann. intern. Med.*, 1945, 22, 543) records his observations on 165 cases of meningococcal meningitis with 9 deaths—a mortality of 5.3%. In 150 cases proved bacteriologically the mortality rate was 4%. Sulphadiazine was the main therapeutic agent, but meningococcus antitoxin and repeated lumbar punctures to relieve intracranial pressure were valuable adjuncts in certain cases.

Reviews

HAEMATOLOGY OF CHILDHOOD

Atlas of the Blood in Children. By Kenneth D. Blackfan, M.D., and Louis K. Diamond, M.D. With illustrations by C. Merrill Leister, M.D. (Pp. 320; coloured illustrations. $12.00 or 66s. 6d.) New York: The Commonwealth Fund; London: Oxford University Press. 1944.

In these days when the emphasis is all on functional rather than factual teaching, the reviewer may well feel an initial prejudice on being handed a large volume on so specialized a subject as the haematology of childhood. Nevertheless, this feeling of prejudice rapidly changes to one of pleasure in handling this exquisitely produced atlas of haematology. The paper, the typography, and the ample margins remind one of the spacious days that have gone. The 70 coloured plates are not only accurate, they are works of art which are as beautiful as a collection of jewels or stamps. It seems, indeed, that in our modern emphasis on function we may be in danger of missing a vital element in medicine—the element that is present in the anatomical plates of Vesalius, in the illustrations to French's *Differential Diagnosis,* in the Hunterian and Wellcome Museums. That element is the drama of fact. The student who looks through this atlas may learn nothing of the venous pressure in profound anaemia or the life span of the erythrocyte, but he will recognize some of the cruellest denizens of the jungle of disease, such as haemolytic anaemia and leukaemia, and he will remember their bright and fearsome images when less vital memories have faded from his mind. In fact it is possible that the recent approach to medical education has been far too rationalistic, and we have been overlooking the importance of interest in making learning easy. The emotions which inspire the collector and the artist have been powerful aids to medical teaching in the past, and we cannot afford to sacrifice such forces when the art is so long and life so fleeting. One cannot help feeling that the average student might get more out of this book on diseases of the blood than out of Sir Thomas Lewis's *Exercises in Human Physiology.* Perhaps there is a tendency nowadays to put the cart before the horse in clinical education, and the student, like the child, might do well to begin with concrete phenomena, with patients and blood pictures, and end up with general principles and abstract reasoning. However this may be, we should like to see this atlas on the table of any department of paediatrics which teaches students. The 144 pages of text are simple and balanced. They are based on experience of more than 5,000 infants and children with disorders of the blood, and even senior haematologists will pick up something of value, as in the advice to give iron salts in fruit juice rather than milk, to avoid precipitation as phosphate; or in the evidence of the transient occurrence of pernicious anaemia in infancy as a result of acute infections and temporary achlorhydria. There is a full bibliography. The book is indeed a fitting memorial to the senior author, Dr. Kenneth D. Blackfan, who died in 1941 after a life largely devoted to the study of the blood in childhood.

BIOLOGY AND HUMAN WELFARE

New Biology—I. Edited by M. L. Johnson and Michael Abercrombie. (Pp. 116; with isotype charts and other illustrations. 9d.) London: Penguin Books.

The Penguin *New Biology—I* contains an astonishing amount of interesting information in a small compass. The editors' aim—helping to re-orientate biology teaching towards questions of human welfare—has been well carried out. It might be thought that the potato was not a very encouraging subject from that point of view, but Dr. R. N. Salaman, a recognized authority, presents us with a fascinating study, beginning with the original culture of the potato in Peru, where it was associated with a horrible ritual of face mutilation to imitate the "eyes." The introduction into Europe of the potato minus the ritual is told, and of the resistance to such a novelty met with everywhere except in Ireland. The social effects of the introduction of a cheap abundant food are discussed, and its influence in keeping wages low. The food value of the potato and its proneness to disease are also clearly described. Prof. Lancelot Hogben gives a somewhat mathematical discourse on the measurement of human survival, while Prof. Walter Stiles contributes an interesting account of the importance of "trace metals" (such as manganese, boron, zinc, and many others) to plant life; yet in more than minimal doses they are injurious. Mr. J. Z. Young records advances in our knowledge of the functions of the central nervous system, from which we learn that the concept of medullary "centres" is being refurbished on a more scientific basis. Prof. Le Gros Clark's article on "the anatomical basis of sensory experience" is complementary to Mr. Young's, and the two form an illuminating contribution. Mrs. Miles's account of the life-history of the wireworm (the larval stage of the click beetle, which takes four years to reach the chrysalis stage) and of the damage it does to agriculture is full of interest. Dr. M. L. Johnson's description of the malaria parasite and the extraordinary complexity of the problems presented by the mosquito is also of great interest at the present time.

This admirable little book is illustrated by plates and diagrams and provided with a glossary. If the editors can maintain the high standard they have achieved, *New Biology—II* will be well worth reading.

OBSTETRICS AND GYNAECOLOGY

Recent Advances in Obstetrics and Gynaecology. By Aleck W. Bourne, M.B., B.Ch., F.R.C.S., F.R.C.O.G., and Leslie H. Williams, M.D., M.S., F.R.C.S., F.R.C.O.G. Sixth edition. (Pp. 358; illustrated. 18s.) London: J. and A. Churchill. 1945.

Midwifery. Principles and Practice for Pupil Midwives, Teacher Midwives and Obstetric Dressers. By R. Christie Brown, M.B., M.S., F.R.C.S., F.R.C.O.G., and Barton Gilbert, M.D., F.R.C.S., M.R.C.O.G. Infants' Section by Richard H. Dobbs, M.D. Second edition. (Pp. 831; illustrated. 15s.) London: Edward Arnold and Co.

The sixth edition of *Recent Advances in Obstetrics and Gynaecology* is a worthy successor to its popular forebears. As stated in the preface there is much recorded in its pages which cannot strictly be classified as coming within recent advances, but the assessment of fact from fantasy is often the more authoritative for that very reason. The passing of time enables the new therapeutic measures of yesterday to be seen in their true perspective and reveals where emphasis has been wrongly placed. The sixth edition contains new chapters dealing with erythroblastosis, vitamin K, stillbirth and neonatal death, and nutrition in pregnancy. Of these particular mention must be made of the chapter on erythroblastosis, which as a lucid summary of the present state of knowledge could not be surpassed. In both ante-natal and post-natal care refreshing emphasis is given to the importance of considering the patient rather than the pelvis. Diet, posture, and exercise all receive the mention they deserve. In discussing cervical carcinoma the authors state that the Wertheim operation and all other operations for the surgical treatment of this condition have become obsolete. The subject is admittedly a difficult one, but it is possible that this is not the final pronouncement that *Recent Advances* will have to make on this subject. The best results so far obtained are not good, and better methods will in time be devised. They may be by irradiation, by surgery, or by a combination of both, possibly assisted by other and newer therapeutic measures. Until such time as the case is finally proven it would be regrettable if the technique of Bonney and his disciples were forgotten.

When a textbook written primarily for midwives is reprinted three times in four years and then is published in a second edition it needs no commendation from a reviewer. It must be gratifying for the authors of *Midwifery* to find that their somewhat unusual approach to the subject has been so widely and favourably received, for their book is no mere collection of facts to be memorized but an interesting and successful attempt to make the reader think logically and arrive at correct deductions from a basic minimum of factual knowledge. The new edition contains appropriate references to the Rh factor in its relation to erythroblastosis and to the dangers of blood transfusion. The work of Caldwell and Molloy on the classification of the pelvis is given considerable attention—possibly more than it deserves in a book of this type will be the comment of some obstetricians. Though there have been some slight additions to the section on breech presentation the authors still do not emphasize the importance of episiotomy in breech delivery. This is a strange omission when advising the inexperienced. Additions have also been made to the sections dealing with ovarian physiology, hormones, labour, drugs, care of the infant, and foetal and placental circulation. The book concludes with a brief but most interesting account of the history of midwifery. It is to be hoped this section will be expanded a little in the next edition.

Notes on Books

We have received from the U.S. Office of War Information (1, Grosvenor Square, London, W.) a copy of the latest edition of a small work of 150 pages, *The Control of Communicable Diseases.* It is a manual of the American Public Health Association, first published in 1916. This, the fifth revision, has been prepared under the expert guidance of a subcommittee presided over by Prof. Haven Emerson. The manual is designed for the use of physicians, nurses, sanitarians, and public health officers in the United States, and since its purpose is to safeguard the welfare of the whole community the emphasis is upon methods of prevention and control. Except for a few illnesses in which a curative drug is also used for prophylaxis, therapy is not dealt with.

Dr. C. P. **Blacker**'s Galton Lecture for 1945, entitled *Eugenics in Prospect and Retrospect,* was delivered last February at Manson House, London, before the Eugenics Society. This interesting lecture has now been published in pamphlet form by Hamish Hamilton Medical Books at 1s. 6d.

The Macy Foundation of New York has published a monograph entitled *Copper Sulfate Method for Measuring Specific Gravities of Whole Blood and Plasma,* by Lieut.-Cmdr. **Robert A. Phillips** and his fellow workers in the U.S. Naval Research Unit at the hospital of the Rockefeller Institute. This includes line charts for calculating plasma proteins, haemoglobin, and haematocrit from plasma and whole-blood gravities. Readers in the British Isles can obtain copies on application to the Medical Research Council, c/o London School of Hygiene, Keppel Street, London, W.C.1.

Volume 68 of the *Transactions of the American Gynecological Society* for the year 1944 is edited by Dr. **Howard C. Taylor**, jun., and published at St. Louis by the C. V. Mosby Company. It is, as usual, a well printed and fully illustrated work and contains nineteen papers and Dr. George W. Kosmak's presidential address; also eleven memorial notices of Fellows who have died. The signed articles have all appeared seriatim in the *American Journal of Obstetrics and Gynecology.* The Society, founded in 1876, has had many distinguished Honorary Fellows: in America there are now living seven, and of the seven foreign Honorary Fellows five are in Britain—Prof. J. Munro Kerr, Dr. T. Watts Eden, Sir William Fletcher Shaw, Mr. Victor Bonney, and Mr. Eardley Holland.

Preparations and Appliances

WIDE-BORE ENDOTRACHEAL CONNEXIONS

Major H. L. **Thornton**, R.A.M.C., anaesthetic specialist with a maxillo-facial unit, B.L.A., sends the following description of wide-bore endotracheal connexions. It was dispatched on Jan. 30, 1945, but went astray.

The endotracheal connexions illustrated in the accompanying photographs have been designed with a view to reducing to a minimum unnecessary resistance to respiration in lengthy operations under endotracheal anaesthesia.

The connexions are of two types, intended for nasal and oral use, the long-axial curvatures corresponding closely to those of the standard Magill's connexions. The overall length of the connexions is 7.5 cm. and the internal diameter of the distal ends is 7.5 cm., equal to the internal diameter of that part of the anaesthetic machine to which the facepiece unions are attached in most standard English patterns. From proximal to distal ends the expansion is smooth and uninterrupted, the proximal ends being slightly larger than the lumen of the tubes to which they are intended to be fitted. A beading at each end is intended to prevent accidental detachment of the connexion in use.

A short length of stiff-walled, wide-bore tubing unites the distal end of the endotracheal connexion to the anaesthetic apparatus without any further constriction or metal-to-metal joint, the latter feature being considered an advantage in obviating a possible source of gas leakage, which so often results from inaccurately fitting or damaged metal joints.

Since the connexions were primarily designed for a type of plastic tube previously described by me in this *Journal* (July 1, 1944, p. 14), the following technique for fitting such tubes to their metal connexions may prove helpful:

1. All grease is removed from the inside of the tube and outside of the connexion with ether.
2. The distal end of the endotracheal tube is thoroughly softened in boiling water.
3. The softened end of the tube is forced well past the beading on the connexion.
4. The softened end of the tube is immediately plunged into cold water and left until thoroughly set.

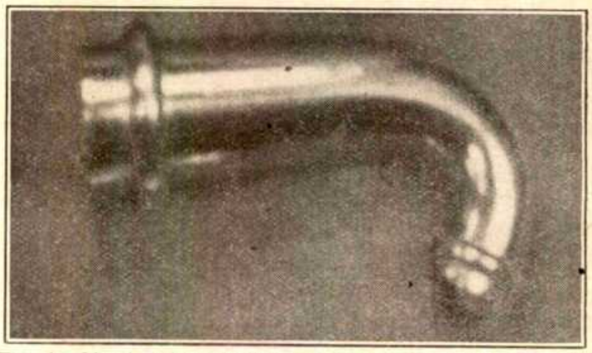

Fig. 1.—Nasal endotracheal connexion for No. 9 Magill's tube (actual size).

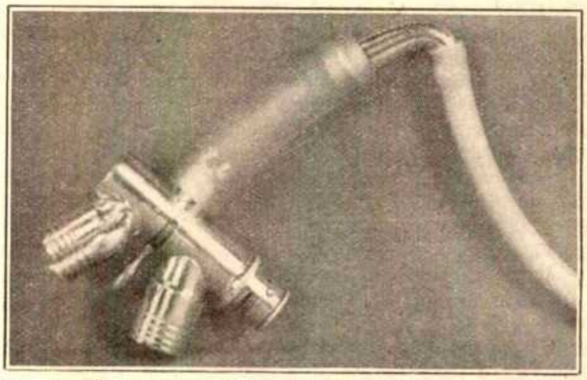

Fig. 2.—Nasal endotracheal tube, wide-bore connexion and union connected to part of anaesthetic apparatus.

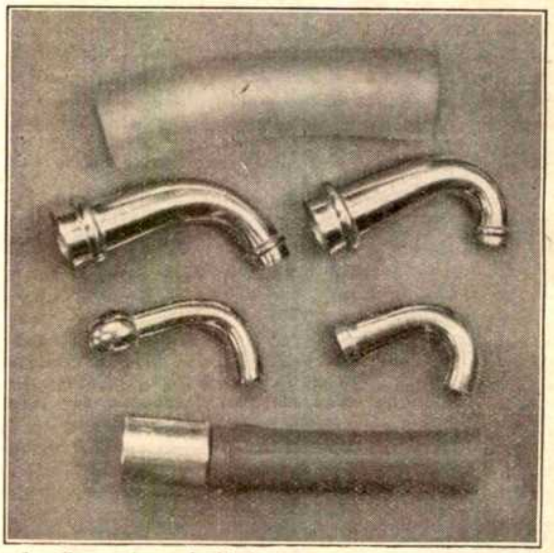

Fig. 3.—Comparison of wide-bore connexions and union (above) with standard Magill's connexions and union (below).

When detaching a metal connexion from a plastic tube it is also necessary first to soften the tube in boiling water.

If these procedures are carefully followed, a firm attachment between tube and connexion can be assured, and splitting or damaging of tubes will be avoided.

I would like to express my thanks to the Director-General, Army Medical Services, for permission to publish this communication, and to Medical and Industrial Equipment, Ltd., for their help in producing experimental connexions.

LONDON

SATURDAY OCTOBER 20 1945

P AND Rh

With increasing knowledge of the serological complexities of human blood groups the hazards of blood transfusion can in expert hands be almost completely eliminated. Reliable anti-A and anti-B grouping sera are now so widely available, and knowledge of blood grouping is so much better generally, that accidents due to wrong ABO groups have become uncommon. Among the other blood-group factors the elimination of risk of incompatible transfusion is now mainly directed against the Rh factor: Diamond[1] has recently stated that among 32 haemolytic transfusion reactions only 5 were due to errors related to the ABO system, whereas 27 were due to Rh incompatibility. The M and N specific substances only very rarely prove antigenic in man; of the eight examples of human anti-M agglutinins hitherto discovered, five were probably natural and three immune iso-antibodies. It is noteworthy that anti-M agglutinins appear to act only at low temperatures (2–5° C.) and not at 37° C.; thus possibly the risk from this factor is minimized.

In the course of work on anti-M sera Landsteiner and Levine[2] encountered both natural and immune animal sera which appeared to make a further distinction between human bloods. The red cell antigen thus recognized they called agglutinogen P. This constituent is present in the red cells of approximately 75% of white persons, but investigation of families is hindered by the lack of potent anti-P sera. Factor P is inherited as a simple Mendelian dominant. A proportion of normal pig and horse sera contain anti-P agglutinins, but both these and sera prepared by the immunization of the common laboratory animals need preliminary absorption of the anti-A, anti-B, and anti-O agglutinins, and the resulting reagents are usually rather weak and may fail to give sharply defined reactions. Iso-agglutinins against factor P also occasionally occur naturally in P-negative human subjects, and when first encountered were called "extra-agglutinin one", by Landsteiner. Later, when found to correspond in specificity with anti-P agglutinins, the old name was dropped. Natural anti-P agglutinins are usually of low titre, but it is probable that they would be increased by the transfusion of P-positive blood. As late as 1943 Wiener[3] stated that transfusion reactions due to anti-P agglutinins had not been observed, though he had encountered two examples of relatively strong anti-P agglutinins in post-transfusion sera. Wiener and Unger[4] have lately described a third example of strong anti-P agglutinins developing apparently as the result of repeated blood transfusions. On the fifteenth day after the first of a series of blood and plasma transfusions, all of which had proved uneventful, difficulty was experienced for the first time in matching the recipient's serum with the corpuscles of a series of donors of his own group (A) and of Group O. The agglutinins were most active at ice-box temperature (titre 1 : 16), but visible reactions occurred at 37° C. A further transfusion of P-negative blood, found to be compatible by cross-matching tests, did not give rise to any reaction, and the anti-P titre rapidly fell. In the investigation of alleged transfusion reactions Cappell[5] has found one man with irregular agglutinins which on the whole corresponded with anti-P, but the reactions were mainly weak and not sharply defined. The evidence suggested that these were natural and not immune agglutinins. There is therefore still no record of a haemolytic transfusion reaction due to anti-P agglutinins, though it seems probable that Wiener and Unger's patient would have experienced one had the cross-matching test failed to detect the irregular agglutinins.

Naturally one thinks of the analogous situation in regard to the Rh factors; the role of iso-immunization in pregnancy and the place of factor P in the aetiology of haemolytic disease of the newborn have to be considered. There does not appear to be any published account of haemolytic disease due to factor P, but inquiry at a number of blood transfusion centres in this country has elicited a small number of cases in which factor P may have been concerned. The Galton Serum Unit, Cambridge, has records[5] of two families in which serological tests on account of previous obstetrical disasters revealed anti-P agglutinins in the mother's serum, the father being P-positive. One of the women was Rh-negative, and an "incomplete" anti-Rh antibody was also present in her serum. The Galton Unit has two other examples of anti-P agglutinins—one from a woman and the other from an infant—but details about these are lacking. At Leeds, Stanbury[5] has encountered two cases of anti-P agglutinins; in one, that of a P-negative mother whose husband was P-positive, the blood sample was submitted during the third pregnancy on account of two previous obstetric disasters. The only surviving child of this woman (a twin) was P-negative; the child born of the third pregnancy was, however, P-positive and did not suffer from haemolytic disease. Stanbury's other example of anti-P agglutinins was detected in the pre-transfusion cross-matching test of blood from a woman who was P-negative, the husband being P-positive. A remarkable feature of this case was that the anti-P agglutinin, as usual more active in the cold, was completely removed from the serum by standing in contact with its own clot in the refrigerator overnight. These may all be natural anti-P agglutinins, but where they already exist the natural antibody in a woman's serum might well be reinforced by iso-immunization during pregnancy with a P-positive foetus; in such women the transfusion of P-positive blood would be likely to provoke a haemolytic transfusion reaction. This catastrophe appears to have been averted in several of the above cases only by the careful cross-matching of the recipient's serum against the cells of the proposed donor. Since, in contrast to anti-Rh agglutinins, for which the tests should be performed at 37° C., anti-P agglutinins react best in the cold, there is a good chance of detecting them in tests at room temperature or, better, at 2–5° C., using the control of the patient's own cells and serum to avoid confusion with cold agglutinins. It is another point in favour of routine cross-matching tests preceding all transfusions, and especially in cases of repeated transfusion from the same donor, in spite of the absence of incompatibility previously. Cross-matching tests alone cannot, of course, be relied upon to detect Rh incompatibility, for the presence of "incomplete" or "blocking" antibodies may mask the presence of anti-Rh agglutinins, and the only safe practice is to ensure that Rh-negative women receive only Rh-negative blood, whether anti-Rh antibodies have been detected in their serum or not.

[5] Unpublished.

Recent knowledge of blood groups and of iso-immunization has thus made it possible not only to safeguard the individual against the dangers of receiving an incompatible transfusion, but also very largely to protect the person against the risk of initiating the process of iso-immunization. Since one person in seven is Rh-negative, the opportunity of sensitizing Rh-negative individuals by transfusion of Rh-positive blood occurs frequently, although in fact only a few will become sensitized to the Rh antigen. The risk to women in the reproductive period of life is particularly great, for the initial stimulus may later be reinforced by pregnancy with an Rh-positive foetus, entailing as a consequence the danger of haemolytic disease. This hazard has not been widely enough recognized, and, further, Diamond[1] has emphasized that the most severe forms of haemolytic disease occur in infants of women sensitized by transfusion. Such catastrophes will not be prevented until it is the universal rule to test for Rh factor every young woman requiring transfusion and to administer only the appropriate type of blood. In obstetric practice the time has come when ascertainment of the blood group, including the Rh factor, should be regarded as an essential part of antenatal care. If obstetricians would co-operate to provide adequate supplies of anti-Rh sera from proved cases of haemolytic disease, it would be possible to instruct obstetric registrars and resident clinical pathologists in the relatively simple tests necessary to determine whether an individual needing transfusion is Rh-positive or Rh-negative, and in the latter case to ensure that only Rh-negative blood is given. The more intricate investigation for anti-Rh antibodies of either the agglutinating or the "incomplete" type is here unnecessary; Wiener's biological test of giving 50 c.cm. of Rh-positive blood and looking for a rise in the serum bilirubin after one hour is slow, and in any event is not without risk if the patient happens to be already sensitized. For practical purposes the subdivisions of the Rh factor may here be ignored, and individuals divided into those whose blood corpuscles react with standard anti-Rh serum (anti-Rh$_0$) who may safely receive Rh-positive blood, and those failing to react with this serum, who should receive Rh-negative blood irrespective of whether they happen to belong to one or other subtype (Rh′ or Rh″). With regard to factor P, preliminary tests to distinguish P-positive and P-negative individuals are not easily available and are unnecessary; the danger of a haemolytic reaction due to factor P is small and is probably safeguarded adequately by careful cross-matching of the bloods at room temperature. In all cases it should of course be an absolute rule not to transfuse any blood which exhibits even a trace of reaction in the cross-matching test.

STUDY OF FOOD HABITS

There is no doubt some good reason why the reading of an American manual on the study of food habits[1] should leave one still groping for definition. Implicit in the pages of the manual is the definition we are seeking; yet it evades us. Perhaps there are temperamental differences, which should be taken into account; perhaps the phraseology is at times unfamiliar. Yet it is worth while to look deeper; and instinctively we turn to the relevant paragraphs of the report on "Nutrition in the Colonial Empire" which appeared in 1939.[2] After all, there is a curious similarity in flavour between these two momentous publications. Do we forget that in the American soil are embedded so many diverse communities—Czechs and Italians, Irish and Chinese, negroes whose remote forebears came from the West Indies, and negroes whose even more remote ancestry sprang direct from the western coasts of Africa? A primitive and undisturbed population may foster food customs that could be improved; but they are customs that have been moulded by tradition to the sources of the food supply; they have acquired a certain measure of balance, an intrinsic survival value. It is when these traditional habits of life have been radically disturbed by the relaxing of the old tribal relationships, by urbanization, by reservations, and by the modes of existence formed in a factory or plantation economy that the real problem of the colonial administrator begins. Food habits are persistent; and rice will be eaten, be it coarsely cleansed in the peasant's hut or polished in the mill. A community of negroes in the United States will attempt to mould such foods as are available towards the traditional pattern. Many modifications are inevitable—in the choice of foods, in the preparation, in the storage. But the persistence of old patterns is strong enough to impart a peculiarly anthropological flavour to the work of the American investigator. His material lies at his own door; allowing for a multitude of differences, his problem is much the same in substance as that which presents itself to our own investigator in Ceylon, Gambia, or Zanzibar.

Needless to say, there is far more to be found in the manual than a mere exercise in anthropological ingenuity; yet here, it seems, lies its point of departure. Here, too, possibly rests our own stumbling-block. In this country there are many variations in food habits and preferences; but few have ventured to study them objectively or to escape the abiding belief that we are all of us, research worker and material alike, woven from the same fabric of traditional prejudices. Objectively we can assess the values of the dietary common to a given sample of families. Vaguely we perceive that ignorance is playing its part;

---

[1] *Manual for the Study of Food Habits*, Bulletin No. 111, published by the National Research Council, National Academy of Sciences, Washington, D.C.
[2] Cmd. 6050, H.M. Stationery Office. (3s.)

but we prefer to round off our inquiry with an estimate at what level of income these families might be expected to purchase an adequate diet; and beyond that we appeal to proverbial wisdom. "The ignorance (and sometimes the prejudice) is not confined to those who are themselves undernourished. It exists also among those who have power over nutrition of others: Government officials, members of Legislative Councils, employers of labour, education authorities, missionaries. . . ." In such a way did our own workers on colonial nutrition prelude their discussion on the factor of ignorance and the need for education. The words may not be written up in our medical schools; but the sense of them affects the trend of our researches. It probably accounts for the fact that in an exhaustive list of almost 700 references the American workers cite no more than 5% that bear upon the study of food habits and preferences in Britain. There have, of course, been many unpublished studies made during the period of war. But the war inquiries were prompted by the official desire to know how the public responded to rationing and to the other wartime changes in our food economy. If this new field of science is to be explored to the full we must necessarily begin by a close study of American methods and experience; yet we must also begin by elaborating our own definition and convincing ourselves that here is a field worthy of exploration.

Let us, then, attempt an essay in definition that may satisfy the temperament of our own workers. A quotation from the American manual will be of help at this point. "Action in a field like this," say the writers (p. 26), "can be taken only on the basis of concrete knowledge. We need to know what sections of the population have what types of food habits, so that steps can be taken either to preserve them or to change them, in part or altogether, so that the population in question will make better use of the available food supply. Experience has shown that the attempt to think through problems of food habits in a cultural vacuum, in terms of abstract psychological principles, is unrewarding." Now, this sentiment is practical; and one can perceive at once that the path to definition must lie through a process of hardening the practical issues. What is it we want to do? Obviously, to begin with, propaganda; and in the course of propaganda to discover what we lack in the way of objective knowledge about the community we are seeking to influence. Let research branch from experience. Temperamentally, in a matter of this kind, we are by nature neither cultural anthropologists nor psychologists. But we are at least anxious that our emerging nutrition services should be expanded to the full; and it is our duty, as medical men and women, to see to it that the wartime improvements in the national dietary are maintained in the period of peace. This is a problem mainly for the propagandist and educationist. Our own inclination would be to subordinate the study of food habits to the sphere of education and instruction; and an appropriate home for a study of this kind might perhaps come within the ambit of such an organization as the Central Council for Health Education, between which and the Food Advice Division of the Ministry of Food a series of practical links could with advantage be contrived.

THE PATHOGENESIS OF TUBERCULOSIS

That the problem of tuberculous infection is still a subject of argument is a measure of our ignorance. It is becoming more than ever necessary to find an answer to such questions as: How is tuberculosis acquired? How may primary and re-infection lesions be distinguished from one another? By what mechanism is the re-infection lesion produced? These can be answered only when careful pathological study has enabled us to form a clear picture of the initial stages of the disease. Terplan's[1] useful contribution to the matter consists of a careful post-mortem study, both anatomical and radiological, of tuberculous patients and those who have died of other diseases. The tuberculous lesions are described in detail, and several facts have emerged which stimulate thought.

Some of his observations seem only to make our problems more difficult. For instance, he finds that a primary focus in the lung can occur without the typical complex involving the regional glands; and that a re-infection lesion can exactly simulate a primary complex. It is even probable that repeated "primary" infections can occur at different times in the same individual. Other findings support the theory that so-called "epituberculosis" in children is commonly the result of bronchial obstruction by tuberculous granulation tissue in the course of the primary complex. Terplan also stresses the frequency of primary infection in adults. An interesting observation by Terplan is the part which the bronchi appear to play in the spread of infection. There is good evidence that localized bronchial spread often occurs in the course of the primary infection, with the production of small caseous pneumonic lesions around the primary focus and elsewhere in the lungs. Again, tuberculous lesions which have resulted from re-infection, as judged by the presence of a separate primary complex, also have pathological features which suggest a bronchial origin. The old theory that secondary tuberculosis results from endogenous re-infection receives no support, because in many cases of re-infection tuberculosis the primary complex was completely healed and obsolete.

The suggestion has been made that the frequent occurrence of re-infection lesions in the posterior parts of the upper lobes may be explained by the fact that foreign material, such as iodized oil, tends to be inhaled into these areas when the patient lies on his back (Bannen,[2] Brock[3]), and that tuberculous re-infection is therefore the result of bronchial embolism. It is, however, difficult to see why the individual should be lying down when he acquires his infection, and Wingfield[4] has pointed out that a minute inhaled droplet might behave differently from a blob of iodized oil introduced artificially. He put forward the hypothesis that repeated inhalations of tubercle bacilli might disturb the immunity balance in the same way as repeated injections of tuberculin. Such a disturbance might increase the activity of bacilli lying dormant in minimal and unrecognized lung lesions. This hypothesis receives some support from the work of Terplan, who found that the scattered lesions produced by bronchial spread from the primary focus often arose in other parts of the lungs and frequently in the upper lobes. Many of these lesions showed a mixture of caseation and calcification, suggesting incomplete healing, and it is easy to imagine a recrudescence of activity in them resulting from a disturbance of the patient's immunity; this would produce re-infection lesions of the "bronchogenic" type described by Terplan.

Thus we can imagine the following sequence of events in the development of tuberculosis. Before the active primary focus has become encapsulated small emboli of caseous material are carried from it by the bronchi to other parts of the lungs. Here they give rise to minute lesions, often too small to be visible in a skiagram, which either heal or remain dormant. A fresh exposure of the patient to large doses of tubercle bacilli then disturbs his immunity so that one or more of these dormant lesions becomes active. This is an attractive hypothesis and seems to fit the facts, but there are still many gaps to be filled. It is a pity that Terplan does not record whether viable tubercle bacilli have ever been isolated from these incompletely healed focal lesions.

CANNED FOODS

In 1810 Nicholas Appert[1] described a new method of preserving foods by heating them in well-stoppered bottles immersed in boiling water. In England, about a year later, John Hall and his associate Bryan Donkin laid the foundations of the canning industry by using this method with iron containers instead of bottles. To-day the annual production of cans for foods runs into many millions, and it is generally recognized that controlled canning is one of the most satisfactory methods of preservation. Flavour, colour, and texture are well maintained; no chemicals have to be added; no special equipment is required for storing the final product, and the housewife has no preparation to carry out beyond re-heating. But what of the nutritional value of canned products? From preliminary work by Kohman and his colleagues in America about 20 years ago results indicated that the value could be rated high. Later, a very thorough experiment on this subject was carried out in Scotland by Godden and Thomson.[2] Working with successive generations of rats over a period of 18 months, they fed one group on nothing but canned foods—including meat, fish, vegetables, fruit, milk, bread, and syrup—and a comparable group on similar foods shop-purchased or locally grown and cooked under household conditions. Throughout the test they found the two groups comparable in all respects—i.e., as regards growth, breeding, and composition of the body as a whole, as well as of teeth and bones separately. One important food constituent was, however, not covered by this investigation. Rats are independent of ascorbic acid in foods, and it was therefore possible that this vitamin might be destroyed by canning. Olliver, however, had shown[3] in 1936 that the loss of ascorbic acid was extremely small, not only for the actual canning process but also for subsequent storage of the can because of the very low oxygen content in the sealed container. It therefore appeared that canning could be regarded as a satisfactory means of preserving all the qualities of foods, including their nutritional value. Further evidence in support of this view was cited by many workers in different countries, the individual vitamins being considered in the majority of the investigations. Both plant and animal products, however, show much variation in the amounts of the different vitamins they contain, due to variation in factors such as maturity, soil, and climatic conditions. Hence it is to be anticipated that, even though destruction during canning may be small, canned foods should show a similar variation. An interesting investigation which has just been completed in America[4] confirms this by the determination in 823 commercially canned samples of the contents of ascorbic acid, carotene, riboflavin, nicotinic acid, vitamin B_1, and pantothenic acid. While, therefore, the efficiency of modern canning processes in retaining nutritional value can be accepted, it must also be recognized that the fixing of standards for the vitamin content of various canned foodstuffs presents very great difficulties.

THE MAKING OF SCIENTIFIC INSTRUMENTS

In 1895 the Cambridge Instrument Company was registered as a limited company, although for seventeen or eighteen years before then it had existed as a private concern. The jubilee is commemorated in a booklet entitled *Fifty Years of Scientific Instrument Manufacture.* The story really begins in 1883, when Michael Foster, who had been appointed to the new chair of physiology at Cambridge, wished to equip his laboratory with apparatus, and A. G. Dew-Smith, a wealthy amateur and a member of Trinity College, came to his assistance and provided a workshop with a skilled instrument-maker. Dew-Smith entered into partnership with Horace Darwin, son of Charles Darwin, and the Cambridge Instrument Company was started. The early workshops saw the making of anthropological instruments for Francis Galton, cloud cameras for Kew Observatory, a temperature regulator for the Board of Trade, and a large range of physiological and physical instruments for the university laboratories. Most of the earliest instruments had physiological or biological applications; some of the most outstanding were microtomes for cutting thin sections of animal or vegetable tissue. A very important chapter in the history of the company is concerned with the manufacture and development of instruments for measuring and recording temperature. The company also played an important part in the development of the electrocardiograph. In 1903 Einthoven of Leyden devised his string galvanometer, which was immediately employed for determining the wave-form and extent of the heart-action currents, and the Cambridge company, in close association with Einthoven, developed a galvanometer with accessory equipment which could be employed, in conjunction with clinical examination, for the diagnosis of heart disease. The development of the Cambridge cardiograph, as the instrument was named, was carried out in close co-operation with Thomas Lewis, and the first complete installation was fitted in 1909. Whereas the original apparatus of Einthoven occupied a whole laboratory, and the electromagnet was enclosed in a water-jacket to prevent overheating, the present equipment is so compact that it can be contained in a suitcase and taken to a patient's house. An account of many other instruments is given, including the apparatus for timing extremely small intervals for the study of nervous impulses, also the device for rendering visible the path of the alpha particles of radium. This illustrated record is much more than the history of a commercial enterprise: it is a footnote to the scientific investigation of the last half-century.

Dr. W. Russell Brain will give the Bradshaw Lecture on "Speech and Handedness" before the Royal College of Physicians of London on Thursday, Nov. 8, at 5 o'clock.

At the invitation of the Ministry of Health and Local Government for Northern Ireland, Lord Amulree of the Ministry of Health, Mr. George Stebbing of the Radium Commission, and Dr. Ralston Paterson of the Christie Hospital and Holt Radium Institute, Manchester, recently visited Northern Ireland. In the course of a few days they visited several hospitals, both voluntary and rate-aided, and had discussions with hospital staffs and others interested in the early diagnosis and treatment of cancer. The visitors expressed the opinion that Northern Ireland offered a particularly good opportunity for the formation of an ideal cancer organization.

REHABILITATION OF PATIENTS SUFFERING FROM SKIN DISEASE

BY

R. MASON BOLAM, M.D.

Major, R.A.M.C.

The subject of rehabilitation has become of increasing importance in recent years in connexion with industrial accidents and disease and in the recovery of members of H.M. Forces from illness and injuries. It has been shown conclusively, for example, that much time can be saved by properly co-ordinated exercises and physiotherapy when a limb has been fractured.

In certain branches of industry, such as coal-mining, a great number of accidents occur each year, and it is noteworthy that both owners and workers contribute large sums of money towards the rehabilitation of miners on an organized basis. This may take the form of gifts of specialized equipment for physiotherapy departments at general hospitals, the financing of convalescent homes, the opening of fracture and accident wards or of hospitals staffed and equipped in such a way as to return the worker to his industry in the shortest possible time.

The Army has found it necessary to provide rehabilitation centres and convalescent depots to which men who have had illness, operations, or wounds are sent to be helped to regain full fighting fitness by mental and physical training of varied and graduated type under expert instructors, with careful medical supervision.

In the last ten years industrial hazards have grown in number and complexity, and many processes connected with the making of armaments, munitions, and aircraft involve the use of powders and liquids that are injurious to the skin. Wartime conditions and service in the Forces have also been responsible for a large increase in the number of cases of skin disease, many of which are of considerable severity and necessitate long periods of treatment in hospital. The effect of service in tropical and semi-tropical climates is often to bring out any latent tendency to skin disease or to accentuate an existing complaint which had not been considered serious before. On the home front, the stress and strain of long hours at work, added to responsibilities from shortage of staff, have caused minor examples of skin disease to assume crippling proportions, so that the patient has been forced to cease work.

In many cases of skin disease a nervous element appears to predominate. Enforced changes in our diet have probably played their part in producing some types of skin disorder, and there has been a big increase in the number of severe cases of seborrhoeic dermatitis. Sulphonamide drugs have proved of inestimable value in the treatment of many different diseases, but they have been the cause of many cases of sensitization dermatitis, which may last for several months and prevent the patient from doing his work. Such cases as these are greatly in need of expert treatment and rehabilitation, and, so far as is known, no attempt has been made to assist them in the stage of convalescence.

The First Experiment

In April, 1943, at the instigation of Brig. R. M. B. MacKenna, A.M.S., some 70 beds were allocated for the rehabilitation of dermatological cases. The auxiliary hospital of the British Red Cross and Order of St. John at Ragley Hall, Alcester, Warwickshire, was the site of this first experiment in the rehabilitation of patients with skin diseases, and the Commandant, Lady Helen Seymour, gave her full co-operation in this new work. From the beginning the hospital has been full. There has been a constant demand from military and other hospitals for beds for skin patients who need a period of readjustment before returning to duty.

The hospital is situated in a historic building in beautiful park land, some 20 miles from Birmingham, and the work is shared by the Matron, two sisters (day and night), nine V.A.D. nurses, an Army sergeant-major, and a male corporal occupational therapist. Medical attention is provided by a local practitioner, who is on call to deal with any minor ailment or emergency, and a weekly visit is paid by the Army Specialist Dermatologist. During the first 11 months that the hospital was open, Lieut.-Col. F. F. Hellier, R.A.M.C., supervised the treatment and rehabilitation, and I have visited the hospital for the past year.

It might be thought, "Why all this fuss about skin patients? They are the last people to need rehabilitation." The subject cannot be dismissed so lightly, and it is only by seeing the patients in the mass, coming as they do from all parts of the country, that one realizes how great is the need of a breathing-space before returning to their former work. One medical officer writes in his case notes: "Skin intact but vulnerable," and this is a very true statement in many instances. The skin itself may be in a tender state and need a little more time to harden off. The patient's spirits are often at a low ebb after an unsightly and depressing skin disease.

The provision of a convalescent hospital expressly designed to cater for subjects of skin disease supplies a long-felt need. It makes possible a study on a group basis of problems associated with rehabilitation and improves the morale of the sufferers. Many of our convalescent hospitals to-day refuse to admit skin patients. This attitude is to be deplored, but this fact strengthens the case for a separate institution to provide sympathetic and expert care for dermatological convalescents.

The psychiatric aspects of rehabilitation of patients with skin disease deserve more detailed study than can be given by the ordinary medical officer. It is obvious that a considerable number of dermatological patients are poorly adjusted from a psychological point of view, and this was borne out recently by Lieut.-Col. E. Miller, R.A.M.C., who visited Ragley Hall and formed the opinion that some of the patients displayed anxiety in varying degree and others were of a pronounced self-centred disposition. In a recent paper he suggests that emotional and intellectual factors should be investigated in those with different types of skin disease, and a survey of the social background of patients, including a genetic study, undertaken. In this way the patient may be helped towards a more complete adjustment to social and economic needs.

Some skin treatment is still necessary for many of those who come for convalescence, and their reaction to graduated exercise must be noted. Special problems have to be solved in deciding whether a man may resume his former occupation; if he may not, then a suitable trade must be found and arrangements made for him along new lines. In all this the utmost tact and sympathy are necessary; the selection of staff for dermatological rehabilitation therefore demands more than ordinary care if a high percentage of success is to be attained.

Procedure at Ragley Hall

It had been noticed that on their arrival at Ragley Hall some of the patients were apprehensive as to what they had come to, but often their fears were allayed when told that this hospital was for skin patients alone. A welcome from the Matron, and an interview with the occupational therapist to find out the inclinations of the new patient towards handiwork, begin the first day. There must be rules when 75 men live together, and certain fatigues have to be performed to help in the smooth working of the hospital; but restrictions are minimal, and careful selection of duties is made, so that no one with tender hands is asked to do any washing or cleaning if he might thereby suffer.

Woodwork, leatherwork, or needlework might be the patient's choice for his handicraft, and it is found in practice that the men become so interested that they spend considerably more time than the two hours allotted daily for this task. Many high-class toys, handbags, wallets, embroidered fire-screens, and fancy belts have been sent to the Red Cross sales or to the patients' homes. Entertainments are held on an average three nights a week and a well-stocked library is kept. Opportunity is given for men to take language or other educational courses, and a lecture is given regularly each week by the Army education authorities. Fresh air is a necessity after confinement to hospital, and the patients have large grounds to roam in and help on farms in the summer season.

After a few weeks the medical officer can estimate the prospects of ultimate recovery, and the disposal of each patient can be decided. No patient leaves hospital without a note to his new unit stating his capacity for work and laying down any further lines of treatment which may be thought necessary.

In this way many men have been saved for the Army by rehabilitation, and a careful follow-up system has been instituted to determine the subsequent fate of the men who have passed through Ragley Hall. During two years' work 800 men have been admitted, and, of these, 584 have been returned to duty and 216 had to be discharged from the Service. Of the latter, 100 replied to a follow-up questionary, and it was found that only three were entirely free from all symptoms and needed no treatment whatever. Five out of the hundred were unemployed.

Types of skin disease which benefit from rehabilitation are: (1) seborrhoeic dermatitis—cases of moderate severity and duration; (2) eczema of mild type; (3) impetigo—severe cases in the stage of recovery; (4) pyodermatitis with debility; (5) furunculosis; (6) sulphonamide dermatitis; (7) lichen planus (needing psychological readjustment).

Seborrhoeic Dermatitis

Cases of this skin disease increased greatly in number during the war years and were seen in various forms, ranging from severe seborrhoea of the scalp alone to generalized exfoliative dermatitis. Seborrhoea of the scalp is found as a complication in cases of acne, impetigo, and eczematous eruptions, and unless due recognition of this factor is noted results of treatment of these three diseases will be only partially successful. One other eruption which is resistant to treatment is otitis externa, and this is almost always associated with definite seborrhoea of the scalp, which must be treated vigorously before the ear condition can be expected to heal.

The cardinal rules in the treatment of the scalp are: (*a*) keep the hair short; (*b*) wash the scalp on alternate days under supervision, using liquid or soft soap; (*c*) apply to the scalp an ointment such as:

℞

Liq. picis carb.	30 m.
Acid. salicyl. Acid. benzoic. Sulph. praecip.	āā 10 gr.
Emulsion base	ad 1 oz.

This ointment to be massaged into the scalp itself by a nurse or orderly and not given to the patient to apply.

Seborrhoeic dermatitis in one or other of its forms is probably the most common of all skin diseases seen in an out-patient department at military hospitals to-day. It is common in the A.T.S. as a dry scaly eruption on face, neck, arms, and trunk, with profuse seborrhoea of the scalp, and among men in the Forces as a papular rash between the shoulder-blades and on the chest which causes marked irritation and is made worse by sweating, heat, severe exercise, and the wearing of thick woollen underwear. Another type of eruption that is becoming more frequent is a generalized papular rash with oval squamous lesions almost identical with those of pityriasis rosea. This is seen in patients of nervous temperament, and if such a condition is incorrectly treated exfoliative dermatitis may follow and rehabilitation may be necessary.

The following ointment has been uniformly successful in the papular and squamous varieties of seborrhoeic dermatitis on trunk and limbs and is much superior to the more popular sulphur and salicylic ointment. It is smeared on gently twice daily.

℞

Liq. picis carb. Calamine Zinc. oxid. Ol. arachis	āā 1 dr.
Paraffin. molle	ad 1 oz.

Eczema; Impetigo; Pyodermatitis; Furunculosis

Eczema is often of constitutional origin; and each case must be considered from this point of view. Once established it will persist and be aggravated by many external irritants. Rehabilitation must include an attempt to provide conditions which will alleviate the severe irritation, and sedatives should be given in full dosage during the phase of recovery. Suitable occupation is all-important and a change of work is often found necessary, so that clerical or light work is substituted for more exposed and arduous conditions of service. Correct underwear and clothing may have to be supplied and limitations imposed on bathing of the skin.

It is a short-sighted policy to return the patient with severe impetigo to full work as soon as his lesions have apparently healed, for he will almost certainly break down and new lesions develop. He has to be admitted to hospital again, whereas a short spell of rehabilitation would have prevented relapse, thus saving time in the long run.

A severe degree of pyodermatitis is often accompanied by scabies, and the latter condition must be looked for with care. If it is not found, then the patient may have poorer powers of resistance to local infection with skin organisms than the average, and time must be allowed for him to build up an immunity. Correct general therapeutic measures should be given as well as local antiseptic dressings. A diet containing a liberal quantity of vitamins should be prescribed, and the addition of food yeast has been found beneficial.

A number of patients with severe and protracted outbreaks of boils have been sent for rehabilitation; a change of surroundings, with continuation of special treatments such as ultra-violet light, vaccine injections, and autohaemotherapy, has enabled men to return to work within a reasonable period. Here again liberal vitamins and the issue of cotton underwear have helped in recovery.

Sulphonamide Dermatitis

Rehabilitation of this class of patient has been of great interest. Some patients have been desensitized to sulphonamides before admission; others have had to be desensitized either to the drug or to light by graduated exposure. In general this type of case does not do very well in the Army, as there is a great hazard in the wearing of khaki overcoat, battle dress, and shirt; and only a certain number of cases of moderate or slight degree are found suitable for the Service after tests in their uniform have been applied. It is probable, from study of follow-up data, that most sufferers revert to normal in the course of time, and if they show no reaction or only a very slight papular rash after a khaki-tolerance test they may be considered suitable for rehabilitation.

Lichen Planus

This chronic eruption is often found in patients with some degree of anxiety state, which must be corrected before work can be resumed and the rash persuaded to regress. The help of a psychiatrist is needed, and a considerable period of convalescence should be allowed. An atmosphere conducive to freedom from worry is usually to be found at a rehabilitation centre, and the patient will generally make a steady recovery. Investigation of the patient's private affairs and continued reassurance are necessary for success.

Conclusion

Many types of skin disease apart from those of a chronic widespread intractable nature will benefit from rehabilitation, and much good work can be done by showing the patient how to live with his disease and apply his treatment correctly. It has been found that facilities for efficient hair-cutting, shampooing, and hair-drying are essential in the rehabilitation centre, and there must be a generous number of baths. Many men have been helped to continue their Army duties by the issue of cotton underwear, and it is considered that the question of suitable clothing for people with sensitive skins needs further scientific investigation.

The above study has shown that (*a*) controlled rehabilitation in Service patients suffering from skin disease is most necessary before they are returned to duty; (*b*) the psychological background of dermatological patients should be the subject of investigation by experts; (*c*) the direction into suitable occupations of men and women who have skin disease is worthy of further study by labour managers; (*d*) rehabilitation of patients with skin disease should be introduced for the civil population.

I wish to thank Brig. R. M. B. MacKenna, Consulting Dermatologist to the Army, for his assistance in the compilation of this paper.

MEDICAL TOPICS AT ASLIB

At the 20th annual conference of A.S.L.I.B. (Association of Special Libraries and Information Bureaux), held in London on Sept. 15 and 16 under the chairmanship of Sir FREDERIC KENYON, a number of papers were presented of interest to hospital administrators, medical librarians, and scientific research workers.

In his opening paper, "Information Service as an Essential Factor in the Progress of Science," Prof. J. D. BERNAL, F.R.S., prophesying that scientific periodical literature at its present rate of output was bound to come to an end, made a novel and provocative suggestion: a prospective author would submit his manuscript to a particular learned society of which he was a member, and the society would then take steps to have his paper published and distributed by a national centre to interested subscribers. The scientific periodical literature of the future would thus consist of individual papers of uniform format, which could be suitably bound according to subject. This scheme, which aims at supplying scientific workers with their absolute minimum requirements, would mean the disappearance from the market of many well-established and familiar journals.

Mr. C. E. A. BEDWELL, formerly chairman of the Guild of Hospital Librarians, described the library for hospital patients as an extension of the home services provided by the public libraries. The patient is a ratepayer in a hospital bed instead of in his own home. Reading has a place in the rehabilitation of patients, and the library should be an integral part of the hospital work. Unfortunately accommodation has not kept pace with the development of the service, and in a great many hospitals in this country a poky little hole without proper shelving or furniture is by an abuse of the English language called a library. Library quarters in a 800 to 1,000 bedded hospital require at least three rooms: one to contain the collection of about 5,000 books and microfilms and seating accommodation for some twenty patients; an office for the library staff; an annexe for trolleys and microfilm projectors; and possibly a room for book repairing—an admirable form of occupational therapy.

Mrs. LUCIA MOHOLY, director of the Aslib Microfilm Service at the Victoria and Albert Museum, described the U.S.A. type of microfilm projector which projects an image of the book on the ceiling for the benefit of a bedridden patient who is not allowed to sit up. While the film has to be fitted into the projector by a nurse or librarian, the patient can operate the machine by himself—with his hands, feet, or slight movement of the head. One or two pages can be shown on the screen at the same time, and pages may be turned forwards as well as backwards. The approximate cost of a projector—the first machine is expected in this country from the U.S.A. next month—will be 100 dollars, and the service will be operated by a non-profit organization in which Aslib will be represented. The speaker mentioned that U.S. publishers have agreed to have their books microfilmed free of royalties for hospital cases and for serious cases nursed outside hospitals. Microfilms have also been used successfully in the education of children afflicted with infantile paralysis. Whether, as was suggested in the discussion, the attractions of the microfilm service might encourage the *malade imaginaire* remains to be seen.

PUBLIC HEALTH TRAINING IN INDIA

A short report has reached us of the work done in the All-India Institute of Hygiene and Public Health, Calcutta, during the years of the war. This Institute was established in 1933, with six sections—namely, public health administration, vital statistics and epidemiology, malariology and rural hygiene, biochemistry and nutrition, maternity and child life, and public health engineering. All these, except the last, functioned from the beginning. The section of public health engineering started in 1938 with the teaching of D.P.H. students as its main interest, but also with research as one of its activities, especially on water and river pollution problems. In 1938 the syllabus for the D.P.H. course as taught at the Institution was found to be out of date as compared with those followed at teaching institutions in Europe and America. Accordingly the curriculum has been revised in keeping with modern demands, especially with a view to the requirements of health officers in charge of rural and urban communities in India, and the amount of teaching given on filterable virus diseases and entomology and on nutrition has been largely extended.

Since 1939 the Institute has been under the directorship of Dr. John B. Grant, who was assigned to that post by the Rockefeller Foundation. Of its wartime activities the most important has been the collection of blood and demonstration of the processing of blood serum through the Calcutta blood bank, which employs mobile collecting teams operating throughout Bengal and has an annual budget of about 3 lakhs of rupees (£22,500). The question of transferring the blood bank to the Provincial Government is now under consideration. Another wartime activity of the Institute has been the training of military personnel in antimalaria work. A large number of subjects are listed as representing problems which have been investigated during the period under review. These include epidemic dropsy, anaemia in pregnancy, tuberculosis, and leprosy surveys in certain districts, typhoid fever in Calcutta, and an inquiry into infant mortality in that city. With the prevalence of severe famine conditions in Bengal towards the close of 1943, the Institute was called upon to help the authorities in relief work. Sample surveys were conducted among destitutes to find out the incidence of infectious diseases such as malaria and dysentery, and help was given to hospital doctors in the treatment of advanced cases of starvation by providing suitable transfusion material.

Industrial hygiene is a subject almost wholly uncultivated in India, but the rapid industrialization of the country makes it imperative that steps should be taken at once to promote hygiene in factories and works, and one of the sections of the Institute is being provided with facilities, through the establishment of a chair, for investigating the problems of industrial hygiene peculiar to Indian conditions.

CHOICE OF WORK FOR HANDICAPPED CHILDREN

The coming into operation of the Disabled Persons (Employment) Act, 1944, and the setting up under that Act of a Register of Disabled Persons will improve the opportunities for suitable employment of disabled children. In order that advantage may be taken of the extended facilities so afforded, the Ministry of Labour and National Service is anxious that its local offices, juvenile employment bureaux, and in certain cases members of disablement advisory committees or of their panels should be furnished with up-to-date educational and medical records of all children leaving special schools and all those leaving other schools who suffer from a temporary or permanent disability which may restrict their choice of employment. It has been the practice of a number of local education authorities to furnish reports on the lines of Forms E.D. 210 and E.D. 211. This latter form is in accordance with the suggestions made in Administrative Memorandum No. 137, dated Sept. 16, 1935. The Ministry of Education hopes that authorities and governing bodies and the managers of voluntary special schools will be prepared to supply information on the lines indicated in these forms in the case of children leaving their schools. The information on these forms should not be communicated to prospective employers.

Where the school medical officer is of opinion that the child may be eligible for registration under the Disabled Persons Employment Act it is suggested that in place of Form E.D. 211 the fuller Form E.D. 211 D.P. should be completed. This form would apply in particular to children leaving certain types of special schools, such as schools for blind, deaf, physically handicapped, and epileptic children, but may also be suitable for a number of those who have been educated in ordinary schools. While the medical officer may wish to complete this form, in the case of certain children, it should not be communicated to the local office of the Ministry of Labour, the juvenile employment bureau, or members of a disablement advisory committee unless the parent has signed the statement of consent included in the form.

Parents might well be told of the improved possibilities of ordinary employment for handicapped persons afforded by the Act, and of the increased facilities for sheltered employment which will be available to registered disabled persons only; and authorities, governing bodies, and managers will no doubt give such advice as they can to enable the parents to judge whether they should sign the statement. Application for Form E.D. 211 D.P., and for additional copies of the other forms, should be addressed to the local office of the Ministry of Labour and National Service.

Reports of Societies

PENICILLIN IN OPHTHALMOLOGY

The session of the Section of Ophthalmology of the Royal Society of Medicine opened on Oct. 11, Mr. P. E. H. Adams in the chair, with a discussion introduced by Prof. Arnold Sorsby on penicillin in ophthalmology.

Prof. Sorsby said that penicillin was commonly regarded as a non-toxic substance and a readily diffusible one. This, however, did not apply in its ophthalmological use, and the eye in relation to penicillin must be regarded as something distinct from the rest of the body. The absence of agreement among observers as to toleration for penicillin was not due to any looseness of observation, but mainly to the fact that samples of penicillin available at the moment were largely impure. Any assessment of tolerance at present was not an indication of tolerance to penicillin, but to samples of penicillin which, though standardized biologically, were not standardized from the point of view of purity.

It was possible to give penicillin in daily subconjunctival injections if the total dosage was not more than 500 or 600 units. He had observed only one case of allergic reaction after the use of penicillin; this was an infant with ophthalmia neonatorum in which the instillation of a drop of penicillin into each eye caused a severe oedema of the lids. A constant corneal bath produced a considerable penetration, and higher concentrations could be reached in the aqueous if ionization were also used, but the combined method was difficult in practice. With ointment it had not been found possible experimentally to obtain any adequate concentration of penicillin in the anterior chamber. If a massive dose were used—something quite beyond the clinical dose—a slight penetration was obtained, but the difficulties with all these procedures was to obtain adequate concentration. With subconjunctival injections a considerable concentration could be reached in the aqueous and vitreous; the drawback was the rapid excretion. By the end of three hours there was hardly any penicillin left in the anterior chamber, and, although the excretion was less rapid in the vitreous, the vitreous was extremely intolerant to injections of any type, and personally he would not inject more than 200 or 300 units. He hoped, however, that ophthalmologists would not be discouraged by these experimental observations. The experiments had taken place in normal eyes in experimental animals, and it did not follow that what applied to the normal eye applied to the inflamed eye. It might seem to be a simple matter to set up an experimental infection of the cornea and to test penicillin in the form of ointment or other method of application. The fact of the matter was that one could not produce a standard experimental lesion of the cornea for these tests. The position was rather different in infections of the anterior chamber, and there was experimental evidence that staphylococcal infection could be influenced by local applications of penicillin, though not in the form of drops.

Local Uses of Penicillin

As for the local uses of penicillin (Prof. Sorsby continued) there was now a voluminous literature. He himself mentioned 123 cases of ophthalmia neonatorum treated during the last year. With 500 units per c.cm., in 8 cases treated there were 3 successes; with 1,000 units, out of 7 cases, 4 successes; with 1,500 units, out of 9 cases, 5 successes; and with 2,500 units, out of 98 cases, 78 successes, 13 relapses, and 7 failures. Penicillin used locally was effective over the whole range of micro-organisms in ophthalmia neonatorum. Frequency as well as concentration was important. When penicillin was applied at intervals of 1 hour the results were good; at intervals of 1/2 hour they were better; at intervals of 5 minutes better still. For technical reasons it was not possible to institute the constant drip, and they were now instilling penicillin at intervals of 1 minute, and in most cases the condition was under control within half an hour.

Penicillin had been used in a variety of eye conditions. Perfectly good control of hypopyon ulcer had been obtained with penicillin drops. Trachoma was a condition in which one would not expect penicillin to be effective, seeing that it was a virus infection. But the virus of trachoma was of a special type, on the borderline between viruses and bacteria. He had tried penicillin in three cases of trachoma, but only one of these was a fresh case, and in this a good result was obtained very rapidly; within four days the typical appearance was lost. Unfortunately, in the other two cases, which were not fresh ones, the results were not at all striking. In iridocyclitis the results so far reported in the literature were not very significant. He had used penicillin in one case of sympathetic ophthalmia with no very encouraging result.

They had in penicillin a powerful agent but a limited one. It did not readily penetrate into the eye. It was of extreme value for local application in external infections. Unlike the sulphonamides, it was not inactivated by pus, and so could be used locally where the sulphonamides were failures. But in intra-ocular inflammation the sulphonamides had not proved very helpful, and penicillin was not likely to be helpful either.

Discussion

In a short discussion Mr. D. V. Giri inquired whether ionization together with systemic application of penicillin had been used in septic inflammation of the eye, to which Prof. Sorsby replied that there was one successful case of post-operative infection reported in the literature. Prof. W. J. B. Riddell asked whether there was any reason why intravenous or intramuscular administration should not be made at such a high level as to ensure that it did penetrate the eye. Was it a question of the supply of penicillin or was there some technical objection? He considered that with modern ointment bases the soapy substance might cause eye damage. Mr. R. Affleck Greeves said that the fact that penicillin did not penetrate the interior of the eye did not necessarily mean that it did not penetrate the tissues of the uveal sac. He quoted a case in which choroidal inflammation had quietened down after penicillin treatment. Mr. C. B. Purvis mentioned a case of blepharitis in which the use of penicillin drops was not successful. Mr. H. Savin was not wholly convinced by the suggestion of specific action in trachoma; he had seen cases show similar improvement under diverse methods. Mr. R. Lindsay Rea said that he had always viewed with trepidation eye conditions in which teeth had to be removed at the same time as the eye treatment. It was useful to know that penicillin could be used during a dental operation.

Prof. Sorsby said that the relapses in his 123 cases of ophthalmia neonatorum amounted to about 18%—very similar to the percentage obtained in about 700 cases treated with sulphonamides. He agreed that even if penicillin did not penetrate into the interior of the eye it might still be of value. It was the ciliary bodies which held back the penicillin. He had no knowledge of what the concentration of penicillin in the ciliary bodies might be, but by analogy it should be extremely high, and it was likely that a good deal of the penicillin diffused back into the choroid, so that any choroidal infection would be influenced, though some observers had failed to obtain improvement in choroiditis. With regard to trachoma, he was not putting forward penicillin as a cure; only as a possibility to be explored.

Mr. H. C. Weston, in his presidential address at the opening of the new session of the Illuminating Engineering Society on Oct. 9, said that there had been a steady rise during the past 25 years in the values of illumination recommended for good lighting, and this had been facilitated by the falling running cost of artificial lighting. The upward trend of recommended standards of illumination was justified by accumulating evidence of the effects of conditions of lighting upon human efficiency. Personal efficiency was one of the indices of health. It was a great mistake to suppose that the meagre values of illumination available with artificial lighting in "the good old days" were adequate for comfort, health, and efficiency. Most of the fine work done by our forefathers—which so excited admiration—was done in daylight, and some of the old craft guilds prohibited night work because it was likely to be bad work. Many people wore spectacles, especially when at work, or they used magnifying glasses; and serious deterioration of vision seemed to have been the rule among those engaged in fine work. The new fluorescent lighting, which had proved such a boon to so many people in war factories and in other places where war service had to be done without any daylight, had not altogether escaped adverse criticism. Much of this was misconceived, and some was due to installation faults and neglect of maintenance. No satisfactory evidence that it had any ill effects upon the eyes had yet been brought forward. Bad or indifferent lighting was still widespread and caused much discomfort, strain, irritability, and loss of efficiency.

Correspondence

R.M.B.F. Christmas Gifts

Sir,—It is my privilege this year to ask you to submit to your readers the Christmas gifts appeal which for so many years has been issued by the late Sir Thomas Barlow and so generously supported by the medical press.

The Christmas gifts appeal has a special significance this year for, although peace has come, the material blessings which peace is supposed to bring are as yet merely dreams without substance. Food is monotonous and scarce; fuel is terribly short and its cost fantastic; clothing and prices generally are on the same high level; and even for those in fairly comfortable circumstances the outlook for the festive season is distinctly drab. Inevitably the burden of high prices and shortage falls most heavily on the poor, and for them there will be little money for celebrations of any sort this coming Christmas.

Last year there was collected a record sum of £1,817, which was distributed as follows: 483 of our people each received a Christmas-gift of £3 at a cost of £1,449. In addition we were able to give 184 of our poorest a further sum of £2 each as a New Year's gift, costing £368. I feel that we must, if possible, do at least as much as last year, and indeed I am pleading for another record. If, for instance, contributions amounted to £2,000, we should be able to give everybody a Christmas gift of £4, and there would still be sufficient over to give some of the poorest an extra £1. Is it too much to ask? A very generous profession has already done so much, but my excuse is the hard times which still lie ahead. Believe me, the gratitude these Christmas gifts evoke is very great and often extremely moving.

Please send your donation, marked "Christmas Gifts," to the Secretary, Royal Medical Benevolent Fund, 1, Balliol House, Manor Fields, Putney, S.W.15, who will gratefully acknowledge it.—I am, etc.,

Arnold Lawson,
President, R.M.B.F.

Dangers of Gastroscopy

Sir,—About twelve months ago an elderly lady, upon whom I had carried out an apparently unsuccessful gastroscopy, developed fever, pain, and surgical emphysema of the neck within twelve hours of the examination. Fortunately she recovered after five days' intensive chemotherapy, but I had no doubt at all that an abrasion of the mucosa in the hypopharyngeal region had given rise to a dangerous mediastinitis. About this time Dr. Avery Jones wrote to me about his case, and at his suggestion inquiry of some other gastroscopists revealed the fact that most of them had had experience of this complication and that there had been five fatal cases. Unquestionably there are others; and Dr. Avery Jones and Dr. Fletcher are to be congratulated on bringing their cases to the notice of the profession (Sept. 29, p. 421).

Gastroscopy is no exception to other forms of endoscopy; it has its own dangers and technique, and patience and gentleness are needed in passing the instrument, especially when dealing with elderly ladies. There is no doubt that the most vulnerable part of the tract lies just above and below the post-cricoid sphincter. Most beginners are aware of the risk of perforating the pyramidal fossae of the hypopharynx, but not so many bear in mind the danger inherent in the prominent anterior curve of the cervical spine when the head is extended, as it must be to pass the gastroscope. The prominence of the spine pushes the posterior pharyngo-oesophageal wall so far forward that the tip of the gastroscope may impinge here with considerable pressure—especially if there is a spasm of the post-cricoid sphincter and the gastroscopist is in a hurry.

In passing the gastroscope the patient's head should be extended no further than is necessary, the operator's fingers should hook the back of the tongue firmly forward, receive the tip of the instrument between them, and carry it downwards, holding it all the time away from the posterior pharyngeal wall until it has passed well over the crest of the extended spine. It may be necessary to do this in stages, momentarily halting the progress of the end of the gastroscope down the pharynx in order to get a new grip with the finger-tips, the better to flex the gastroscope forward as it goes. Even when all appears easy the instrumentation must be done *slowly* because the mucosa may be dry from pre-operative scopolamine; for the same reason the *whole* of the rubber part of the instrument must be well lubricated, because a simple abrasion of an atrophic mucosa may be quite sufficient to give rise to a mediastinitis.

Notwithstanding all precautions, risk of mediastinal infection will continue to be a rare but definite possibility among the thousands of gastroscopies annually performed. For this reason I am generally averse to performing this examination on out-patients. Whenever possible the patient should spend the night before in hospital and be properly prepared the following morning. The quietude of the patient's mind that can be assured in this way makes the gastroscopy easier to perform and greatly diminishes the likelihood of spasm and abrasion of the hypopharyngeal sphincter. After the morning gastroscopy the patient should remain all day in hospital under observation until the evening, when he may be discharged if all is well. If there should be any suspicion of an oesophageal abrasion the patient should be retained in hospital on sulphonamides and penicillin lozenges. Success in treatment depends entirely on the promptness with which it is applied. I have practised this régime of 24-hour hospitalization and supervision for the last nine years at the London Hospital, and I feel it to be a reasonably adequate safeguard against both the incidence of, and the failure to detect, oesophageal lesions after gastroscopy.—I am, etc.,

London, W.1. Hermon Taylor.

Excision of Patella

Sir,—Fracture of the patella is not uncommon in the Services, and Mr. H. A. T. Fairbank's letter (July 14, p. 62) should be heeded by all who are called upon to deal with this injury. The ugly knee that follows excision is rarely a normally functioning knee, and no one should perform the operation unless to the infantryman he is prepared to say: "You are unlikely to become fit for full marching"; to the gunner, "You should not expect to be able to lift the heavy weights you used to do."

However, excision is the only possible treatment for the severely comminuted patella. In operating on such cases I would stress the importance, first, of removing every particle of bone and periosteum; and, secondly, of making every effort to close the rent in the capsule with synovial membrane. This may require the freeing of the suprapatellar pouch—a dissection to be performed carefully and without hurry. The tissue made available will permit accurate closure of the largest gap.—I am, etc.,

S.E.A.C. J. H. Milnes Walker.

Fenestration for Otosclerosis

Sir,—I agree with the writer of your leading article on fenestration for otosclerosis (Sept. 29, p. 430) that a full review of the subject is opportune, but I should like, if I may, to offer a few criticisms of his article.

It was, I think, unfortunate that a popular American monthly, with a circulation of several millions in the English-speaking world, should have published a highly coloured and optimistic article on the fenestration operation as a cure for deafness a few months ago. I had several copies of this sent to me, with inquiries, while I was still in the Army, and since my release no week has passed without further inquiries about the desirability of this operation or even the possibility of proceeding to America to have it performed. Your leader-writer has, I am afraid, done little to dispel the results of this indiscriminate publicity, or to clarify the present situation with a view to helping the general practitioner to advise his patients on the subject. He speaks of "a technique which promises to give 80% of good results," then quotes Shambaugh as claiming "a 90% chance of lasting improvement and a 70% chance that this improvement will equal or surpass that obtained by a hearing aid," and goes on to say, apparently in his own opinion, that "it may be accepted that rather less than half (probably about one-third) of the patients treated by this technique have gained real benefit," and warns that "an exact percentage of successful results is not easy to estimate."

As it is evidently difficult to evaluate the indications for operation and the results of the various American authors quoted by your leader-writer, it is all the more surprising that he has altogether neglected the work done in this country. I do not refer to the sporadic labyrinthine operations by various otologists following Jenkins and Holmgren some years ago, but to the report of a series of 66 cases by Mr. Simson Hall of Edinburgh at a meeting of the Section of Otology of the Royal Society of Medicine in March, 1944, followed by a well-informed and animated discussion (*Proc. roy. Soc. Med.*, Oct., 1944, **37**, 737; *J. Laryng. Otol.*, July, 1944, **59**, 255). Mr. Simson Hall pointed out that selection of cases had a great deal to do with the results, and that there were the following common characteristics in those showing improvement: the patients were young, usually under 30; deafness was not extreme; there was no sign or history of middle-ear disease, and no nerve deafness. He considered that lack of appreciation of the upper tones by bone conduction had proved a contra-indication to operation, and he now refused such patients for operation. Mr. Simson Hall had had 66 cases in six years, and after eliminating his earliest cases because of faults in technique, and his latest cases because of too short a period of observation, he arrived at an improvement in 51%, but considered that figure of but little practical value; of the cases operated on prior to 1940 36% had retained their improvement in hearing; he had one death, apparently due to an idiosyncrasy to morphine.

The contrast, of course, is marked with the 1,000 fenestration operations for otosclerosis in seven years by Dr. Lempert of New York—more cases of otosclerosis than most European otologists of experience are accustomed to diagnose in a lifetime; 74.4% of Lempert's cases showed what he calls "complete or partial rehabilitation for social and economic contacts," but no fewer than 616 of his cases were operated upon less than three years ago (*Arch. Otolaryng.*, Jan., 1945, **41**, 1). Dr. C. E. Kinney, in a recent review of the subject (*Laryngoscope*, March, 1945, **55**, 117), based on a personal series of 32 cases and a careful critical estimation of the literature, though stating that in his opinion the operation is "a distinct advance in the therapy of the disease," points out the difficulty in selecting cases, the difficulty in evaluation of results and in technique, and concludes that "the claiming of 85 to 90% of successful results is unwarranted at this time." Yet when one has witnessed (as I have done in Mr. Simson Hall's clinic) the drama of seeing the membranous labyrinth exposed under local analgesia, and a previously deaf patient eagerly repeating the aural surgeon's whisper from the farthest corner of the operating-theatre, one admits that it must be difficult for the surgeon to retain the sobriety of his judgment and to damp down his enthusiasm for several years, until the end-result of the operation can be properly evaluated.

As I have spent the last five years—the most important period in the development of this operation—in the Army, I need hardly say that I have had no personal experience of it, nor am I likely to have until I get more certain information about the selection of cases, a more riskless technique, and a more definite promise of improvement in hearing. If my opinion were asked, I could not conscientiously advise a patient suffering from otosclerosis to-day to undergo this operation without explaining the uncertainty of improvement and the undoubted risks that accompany any operation on the labyrinth. Far be it from me to discourage any of my colleagues in their researches to relieve deafness by operation, but it is as wrong to encourage young otologists to dash into a fascinating technique without careful and prolonged training in the surgery of the labyrinth as it is to raise the hopes of the deaf by ill-judged optimism.—I am, etc.,

London, W.1. R. SCOTT STEVENSON.

Treatment of Denuded External Skull Table

SIR,—The interesting account of this subject by Majors P. Clarkson and J. Schorstein (Sept. 29, p. 422), and the excellence of the result, call to mind a somewhat similar case. Although the conditions differed materially in that there was no interval before grafting and this was done to the bare outer table and not to the diploe, the blood supply to the skull is so good that evidently success may be expected by any clean method.

A man of 70 years was admitted to the Royal Infirmary, Aberdeen, in 1912 under Prof. Marnoch with a horribly offensive, ulcerated epithelioma of the whole of the right pinna, destruction of the tympanum, extensive glandular involvement, and severe pain and sleeplessness. There was no sign of intracranial growth. The external carotid was ligated at its origin, and a wide block removal of all the affected structures, including the parotid, facial nerve, and internal jugular vein, was carried out down to the skull, from which the periosteum was stripped. The mass measured 6 inches vertically and 7 inches horizontally. This area was immediately and completely covered with autogenous Thiersch grafts, most of them being applied to the bare squame and parietal, which did not bleed. Every graft took completely. There was always a small sero-purulent discharge with a little wax from the bony meatus and complete facial paralysis, but no other surgical imperfection developed and the eye was preserved. The graft remained intact and without scaling or ulceration. A small "deer-stalker" flap from the cap was worn to mask the deformity. The condition was said to have begun where the spectacle frame irritated the skin. So far as I can remember the patient lived some five years in great comfort and with no sign of recurrence. He frequently came for examination. He died of bronchitis.

The grafting of skin direct to bare bone was new to me at the time and was tried because it was the obvious thing to do. Had it failed a plastic operation could have been done and the deformity filled up. Beyond an occasional opportunity to prevent scarring in temporary amputation stumps no further trials of the method have been made. A good application of the method would be in cases of scalping by machinery. The saving of suffering and time would be enormous, and it appears that a wig would not cause the graft to scale or ulcerate.—I am, etc.,

London, W.1. G. H. COLT.

Treatment of Duodenal Ulcer

SIR,—As one whose lot it has been to see and treat very large numbers of cases of duodenal ulcer during the past fifteen years, I have at various times tried what Sir Adolphe Abrahams (Oct. 6, p. 473) calls "this, that, or the other 'cure' for duodenal ulceration as an incident in ambulatory treatment." As a result of my experience I am convinced that there is no "short cut" to cure, and that the most successful and lasting results are obtained by the orthodox diet, alkalis, and supplementary vitamins B_1 and C. I can fully endorse his statement that "almost incredible remissions are a familiar experience."

It has to be recognized that there is, what I called many years ago, such a thing as a "duodenal diathesis," though that is not to say that every case of duodenal ulcer necessarily presents the stigmata in obvious form. For this reason I make it a rule to warn all "recovered" cases—i.e., when symptom-free with radiologically confirmed healing—of the possibility, even the probability, of relapse; of the importance of adhering to a "healed ulcer" regime; and of the need for a periodic survey even in the absence of symptoms. I would particularly emphasize the latter.—I am, etc.,

Brookwood. H. M. STANLEY TURNER.

Sciatic "Neuritis"

SIR,—I was much interested in the article on sciatic "neuritis" by Dr. Holmes and Mr. Sworn (Sept. 15, p. 350). They say: "It is now generally accepted that the commonest cause of chronic pain in the distribution of the lumbo-sacral nerve roots is a rupture of a lumbar intervertebral disk, but there has been much discussion during the past few years between the exponents of the 'disk' and 'neuritis' theories of the causation of lumbo-sacral root pain.... Symonds (1943) has stated that 'the vision of an inflamed and swollen sciatic nerve, so confidently stated to be the cause of the syndrome in question, has never yet been granted to human eyes.'"

They describe three cases in which there had been severe and continuous sciatic pain for a considerable time before operation, but in neither of these was there any sign of a swollen disk or of any mechanical pressure on the nerve roots. In one case the swelling of the nerve was so great that the presence of a neurofibroma was suspected, but on incision it was found to be swollen and oedematous. All these patients had very severe pain for a week or more after the operations, which gradually subsided, and they have been quite well since. One, a miner, was able to return to full work in the mine. The authors admit that at present they cannot distinguish cases of sciatic neuritis from those with a ruptured disk, without an operation, but for the moment must be content with having seen a lesion which Symonds declares "has not yet been granted to human eyes."

I can have little doubt that if instead of an immediate surgical procedure oxygen were injected subcutaneously as described by Drs. J. P. Martin and James Collier and mentioned in my letter in the *Journal* of Feb. 12, 1944 (p. 230), not only would there be no pain at the time, but the severe after-pain lasting for a week or two after the operation would be entirely avoided, and the sciatic neuritis might even be entirely and permanently cured. The diagnosis of sciatic neuritis should present no difficulty. As Dr. Collier says in his article in Price's *Textbook of Medicine*, third edition, page 1654, there is tenderness on pressure over the nerve at the back of the thigh, and severe pain is caused by stretching the nerve, by extending the knee with the thigh flexed; and by various other simple methods. It may well be, now that peace is once more restored, sciatic neuritis will be recognized by all and its treatment by injection of oxygen may again be restored to favour.—I am, etc.,

Worthing. HERBERT H. BROWN.

Stovaine Anaesthesia

SIR,—Mr. K. E. Madan (Oct. 6, p. 474) has raised a point regarding stovaine which should by now be generally known. It is a pity that Chaput's solution of stovaine (10%) in saline was called the "light" solution, although it is undoubtedly hyperbaric, and with suitable posture of the patient can be used for giving either a high or low spinal anaesthetic. The correct facts regarding this solution have been presented in all three editions of *Principles and Practice of Rectal Surgery* (1932, 1937, 1945).—I am, etc.,

London, W.1. W. B. GABRIEL.

Mode of Action of Vitamin D

SIR,—In the annotation on the above subject (Sept. 29, p. 432) one is left in doubt as to what rickets is considered to be and what exactly vitamin D does and how it does it. The impression created is that rickets is thought to be the result of calcium deficiency. Deficiency of available calcium, whether due to actual lack as such in the diet primarily or secondarily and paradoxically to an alkalosis brought about by the administration of considerable (but not excessive) amounts of calcium as the carbonate, gluconate, and the like, produces osteoporosis not rickets. Osteoporosis is also caused by the administration of calcium salts of the strong acids such as $CaCl_2$, in which case the underlying factor of causation is the appearance of acidosis.

Vitamin D has no effect in curing or preventing osteoporosis due to actual lack of calcium in the diet. As will be discussed immediately, its remedial action in the alkalotically produced variety is due to the production of acidosis with consequent increased formation of HCl in the gastric juice (to reduce the acidosis) and resultant increased absorption of calcium as $CaCl_2$, with its subsequent retention in the bones and tissues as the phosphate. I am not aware of the effect, if any, vitamin D has on the acidotic osteoporosis due to $CaCl_2$ administration. Calcium phosphate, however, as a source of calcium (but not of phosphate) can be added to the diet in considerable quantity without baneful effects.

The routine method for production of rickets in experimental animals is by the feeding of a diet containing an excessive amount of $CaCO_3$—e.g., the Steenbock and Black rachitogenic diet No. 2965, which contains 3% $CaCO_3$. The phosphates of the food as soon as they are liberated are thus precipitated in the intestine and so prevented from being absorbed, with the result that there is an actual phosphate deficiency in the tissues. Such a deficiency, of course, occurs also when there is an actual lack of phosphate in the diet. In both circumstances rickets is produced; and it has to be emphasized that this is a condition which, contrary to the view held by chemists who, many in number, have no inhibitions about carrying on investigations into abstruse problems in pathology, cannot possibly be differentiated from osteoporosis by means of *x* rays or chemical analysis but only by histological examination.

As I have pointed out on several occasions (1–7), the evidence goes to show that vitamin D, in curing rickets brought about by either of these two methods, does so by setting free phosphoric acid from its combination with glycerol, fatty acids, and choline in the phospho-lipins, thereby liberating it in its nascent state in the tissues and so anchoring calcium; and instituting an acidotic condition which, by increasing HCl in the gastric juice, facilitates the early absorption of calcium as $CaCl_2$ and so prevents it precipitating the phosphates set free later on from the food, which consequently are absorbed and metabolized.

As stated in the annotation, Cohn and Greenberg, using radioactive phosphorus, showed in 1939 that vitamin D aids the conversion of organic to inorganic phosphorus in bone—a result which appears to be confirmation of my view. It is necessary in the present context to add that on several occasions[8 9 10] I have pointed out that, since Sir Edward Mellanby did not produce rickets in his experimental dogs, he could not possibly have shown that cod-liver oil cured the disease; and further that, according to his own showing, cod-liver oil did not cure the condition he actually produced, which was, in fact, osteoporosis due to deficiency of calcium in the experimental diet. His suggestion at a later date that phytic acid precipitates calcium in the intestines, and so prevents its absorption, if entertainable at all, has relation to the production not of rickets, as he claims, but of osteoporosis.—I am, etc.,

Aberdeen. J. P. MCGOWAN.

Nerve Injuries in Children

SIR,—I think that there must have been a misprint or clerical error in Mr. E. Hambly's letter (Oct. 6, p. 474) on this subject. He states that the median nerve recovered at the rate of 15 mm. a day. He examined the case at the sixth week, but at the quoted rate of growth from a lesion 1½ in. above the wrist the axons would take only 14 to 16 days to reach the tip of the third finger! Actually, a rate of 3 mm. a day would bring axons well on to the thenar eminence at 4 weeks. The "latent period" clearly has not been allowed for in these calculations, but, presumably, as the wrist was in plaster it was not possible to assess the time of onset of an advancing Tinel's sign, and it is therefore difficult to understand the figures given.

Admittedly lesions in children and lesions near the periphery recover rapidly, but even so I think 15 mm. a day would be found by Mr. Hambly, on reflection, to be erroneous.—I am, etc.,

Dunston-on-Tyne. F. G. ST. CLAIR STRANGE.

SIR,—When claims are put forward that nerve suture has been followed by recovery at a phenomenal rate, it is well to consider whether there has been a mistake in the arithmetic. In the case cited by Mr. E. Hambly (Oct. 6, p. 474), claiming a rate of recovery of 15 mm. a day, the error is clear. "The lesion was 1½ in. [4 cm.] above the wrist." "Return of sensation occurred over the thenar eminence [in a child not more than 4 cm. below the wrist] at the sixth week." 8 cm. had been covered in six weeks, and the rate of recovery is therefore 80/42—just less than 2 mm. a day. This figure is confirmed by the further statement that "general sensory recovery had occurred by the twelfth week." Presumably this means recovery of sensibility as far as the terminal phalanges. In children aged 14 the distance between the wrist and the centre of the terminal phalanges averages approximately 14 cm. The rate of recovery must be 140+40/84, or 2.1 mm. a day.—I am, etc.,

Headington, Oxford. R. B. ZACHARY.

Longevity

SIR,—The investigation into longevity and old age in the Punjab by Dr. M. Yacob and Mr. S. Swaroop (Sept. 29, p. 433) prompts me to bring up certain material which I came across when looking up the literature on longevity in 1940.

It is admitted that there is "a considerable lack of accuracy in age records." As regards Thomas Parr, subject of a post-mortem examination by William Harvey, Thoms and Young found no trace of his birth in diocesan records, and his age rests solely on his own assertions and those of his publicity agent—the poet John Taylor. As regards Henry Jenkins, his age is said to be authenticated by appearance in Chancery records 143 years before death, and by his disposition as a witness at the age of 157; but even official records do not exclude the possibility of the witness at 157 being the son of the man in the Chancery case. Most of these ages rest on parish records, which are liable to unintentional errors. Prof. Pearl cited an imaginary case in this connexion: a child was born, called John Smith, and was baptized, dying at the age of 15; in the same year the parents had another male child, called John in remembrance and never baptized; thus if the latter lived to 85 baptismal records would show him as 100.

I think it may be safely taken that ages greatly over 100 are not satisfactorily authenticated. The most reliable method—namely, compulsory registration of births—only came into force in England in 1837, and this discounts any present ages over 108 years. The ages quoted by Basilievitch and others giving the number of centenarians in the Abkhasian Autonomous Republic of Georgian S.S.R as 3,792 per million, as against ·5 to ·6 in Denmark, to quote one European country, are unbelievable. (The population on which this was based was 210,000, so that statistically these figures are misleading.) Even British census figures are misleading, as really old people take a not unnatural pride in overstating their ages, for how else could the relative deficiency in persons aged 85 to 90 as compared with those over that age be explained in the 1911 census (King)? Working on the 1931 census figures, *not more* than 3.91 persons per million are centenarians, and it will be noted that this figure corresponds to 5.03 and 3.055 in 1891 and 1911 respectively, thus reflecting an increased accuracy in the census.

As regards increase in expectation of life as an assessment of longevity, it should be noted that, whilst expectation of life in England and Wales has increased by 15.7 years (17.73 in the case of females) for males between 1854 and 1922 *at birth*, this is mainly reflected in decreased infant mortality, the standardized death rates falling by only 14% for ages 85 upwards between 1841–50 and 1931–5, as against an overall fall of 55.6%. This means only an increase of months after the age of 40. The English figures also confirm throughout the "general experience that females have a longer duration of life than males," the standardized death rates being lower at all ages. This being so, it is rather dangerous to assess longevity in different countries on expectation-of-life figures. The table by Pearl (1930), based on percentages of population over 50 years of age, puts British India third for males (19.2%) but twenty-first for females (12.4%), the figures for England and Wales being 18.4% and 19.6% respectively. To some extent, therefore, this corroborates the poor prospect of female longevity in India.

It appears definite that the main factor in longevity is hereditary (Rush, 1849; Pearl, 1934); but it is unknown how this is transmitted. Environment may play some part, and formerly it was noted that rural life was more conducive to longevity; but the gulf has largely narrowed, and figures from the *Statistical Review* for 1938 were much the same as each other. Nevertheless, one would not expect the figures in Death Valley, California, to be so propitious as those for more amenable climes. Serious illness, if complete recovery occurs, does not appear to be a bar to longevity (Humphrey, 1889). Nearly all centenarians have been married, sometimes more than once, but what this means is doubtful except that it might be said that the long-livers enabled their natural instincts play and so led happy and contented lives. Similarly the contentment of tobacco and alcohol *in moderation* may lead to longevity (Pearl, 1928, 1938). Occupation is said to be a factor, as in the exposure of doctors to worry and infection, but Drinkwater found the average age of 2,113 eminent doctors eight years higher than the average age of the adult male population over 21; however, there are so many factors operative in a comparison of this nature that it is difficult to draw conclusions withstanding statistical criticism.

To sum up, therefore, we must hesitate before accepting extreme figures of alleged old age. There are plenty of these, and I, personally, collected records of 567 of them from various sources in Northumberland, Durham, and Yorkshire. Like Parr, they ranged up to 148 and lacked satisfactory confirmation. Patrick Wian, for example, vicar of Lesbury, lived to over 120, but there is no memorial or other records in his parish church, although he should have been buried in the chancel (*Monthly Chronicle*, 1887). Their stories are interesting for the alleged return of various faculties after previous deterioration; the cutting of new teeth and their various eccentricities. There is the story of Simon Ellerton, who reached 104, and often walked to London (!), carrying back on his head the most suitable stone he could find wherewith to build a house. After his house was completed he continued to do so, telling inquirers "it was to keep his hat on." But these stories would fill a book.—I am, etc.,

Seaham. A. Forster.

Estimation of E.S.R. at Sea

Sir,—No reference has been found in the literature to the erythrocyte sedimentation rate being used at sea. It was considered that this test might prove of greater value on board ship, where *x*-ray and other laboratory facilities were absent, than it does in hospitals ashore.

Before the test could be used for patients it was necessary to ascertain whether it could be carried out with reasonable accuracy in rough seas and at speeds where engine vibration was in evidence. A small series of healthy controls were tested under three conditions: (1) while the ship was alongside prior to sailing; (2) while steaming at high speed; and (3) in rough seas. These three estimates gave very similar results for each control, all being within normal limits. The investigation was subsequently carried out on patients.

To be of use at sea elaborate apparatus to overcome vibration, etc., is not applicable, and simplicity is essential. The method utilized was the following. The ordinary three-tube Westergren stand was used with the centre tube removed. A string was attached to the deck head at one end and a loop tied at the other. The stand with the two side tubes *in situ* was suspended by passing the loop of string over the middle metal clip so as to lie *at the junction of the metal clip and the upper cross-bar* of the stand. This resulted in the tubes remaining perfectly vertical, as tested by an improvised plumb-line. If the string is attached to the cross-bar itself the weight of the tubes and stand platform (both anterior to the cross-bar) prevents the tubes remaining absolutely perpendicular.—I am, etc.,

Medical Aspects of Prisons

Sir,—Recent correspondence (July 21, p. 100; Aug. 18, p. 242) has again thrown some doubt on the adequacy of our prisons from the medical and hygienic standpoints. The recent Home Office report on *Prisons and Borstals* (1945) is of interest in this respect. A careful study of the report does not support Dr. Sass's statement (Sept. 1, p. 301) that in our prisons "sanitary conditions are not primitive," and substantiates much of "C.438's" evidence. Certain medical aspects of the report which are highly unsatisfactory have already been noted (*Lancet*, Aug. 4, p. 145)—e.g., the prison diet, probably deficient in vitamins; the primitive forms of punishment, which include a "restricted diet" (1 lb. bread per day with water); flogging, and the removal of a prisoner's mattress for 15 days; and the frequent failure to provide psychiatric treatment, even where this has been specifically recommended by a court.

Judging by the report certain other features of our penal system call for particular criticism from the psychiatric point of view. Thus, prisoners are locked up in their cells from

5.30 p.m. until 6.30 a.m. Again, to quote the report, "a large number of prisoners are employed in no more arduous or interesting work than sewing mailbags. . . . Many indeed are in prison just because of their mental and physical unfitness to earn a living. There can be no question here of teaching a trade." One of the punishments is confinement to the cell up to 28 days; "if violent or refractory" the prisoner "may be placed in the 'special cells,' which are sound-proof and fitted with unbreakable furniture." The latter statement suggests that the authorities may be far more concerned with the care of inanimate objects than with that of the unfortunate man suffering from a "prison psychosis." It is also stated that the conditions of a prison are such that the segregation of young prisoners from adults—and among the former the separation of convicted and unconvicted, first offenders, and recidivists—cannot be satisfactorily effected; and that the conditions for girls are "even more unsuitable." Further, the allocation of young delinquents to the various types of Borstal institutions appears to be somewhat arbitrarily carried out, according to "age, development, record, and general make-up," which, even to a skilled psychiatrist, would often be meaningless and misleading criteria for evaluating intelligence, ability, personality, psychopathology, etc.

At a time when public and authorities alike are expressing growing alarm at the high incidence of juvenile delinquency it must cause some concern to the medical profession that there has yet been so little official recognition (or, indeed, cognition) of the great advances which have been made in recent years by psychiatry in the understanding, treatment, and prevention of antisocial behaviour. Such obsolete methods are still applied to delinquents as would not to-day be tolerated in the treatment of physical, or other forms of mental, illness. In spite of undoubted progress in our penal methods in the past 50 years, the authorities still remain far behind contemporary psychiatric, educational, and sociological research in the field of criminology (not to mention dietetics). This remains true even if we take into consideration admitted administrative difficulties due to the obsolete prison buildings, their wartime overcrowding and understaffing, and the (presumably) temporary suspension of the Criminal Justice Bill introduced in 1938.

An adequate official reconsideration of these matters is all the more urgently required when we recall the recent decision of the Home Office to use Dartmoor (already condemned as a prison) as a Borstal institution. This has aroused the justifiable criticism that "no surroundings could be better calculated to develop in the minds of boys and young men confined there the sense that they are . . . an inferior caste . . . bound to make war on the community when liberty gives them the chance" (*Times*, Oct. 3). It is indeed somewhat paradoxical to read Mr. Herbert Morrison's introduction to the report, stating that the methods there described "seek not to repress but to reform, not to humiliate but to restore . . . an individual's share in what is good and valuable." The medical profession, and psychiatrists in particular, may perhaps think otherwise.—I am, etc.,

Warlingham Park Hospital, Surrey. R. H. Ahrenfeldt.

Diet in Morphine Addiction

Sir,—A striking feature of the case described by Drs. Charles Comerford and B. H. Kirman in their article on pellagra in a morphine addict (July 14, p. 44) is that, in spite of the patient's having been an addict for 12 years, "no morphine was given, and after the first day no sedatives . . ." yet in eleven days she "improved considerably and put on weight." In my experience long-standing drug-addiction cases require a certain amount of the drug of addiction during the first 24 to 48 hours of treatment or replacement of the drug by other sedatives, and in no circumstances have I ever known a patient to gain weight in the first two weeks. The marked physical restlessness and mental distress occasioned by deprivation of their drug militate against any increase in weight, even when insulin is used to produce an artificial appetite.

The patient's statement that she was not taking any morphine or alcohol 16 months after her discharge from hospital would be discredited by most physicians experienced in the management of drug-addiction cases, especially in the light of her failure to co-operate in out-patient treatment so far as vitamin concentrates and adequate diet were concerned. The craving for morphine is the most urgent of all, and it is extremely unlikely that a patient who was uncooperative in any respect would resist that urge. All drug addicts lose weight and yet remain remarkably free from intercurrent conditions, which may account for the infrequent association of drug addiction with other morbid complaints.

It is not quite clear from the account whether or not the patient received any treatment during her eleven days' sojourn at St. Alfege's Hospital. Intensive vitamin therapy has been found valuable in alleviating deprivation symptoms, but alone could scarcely account for the patient's "reasonable and co-operative" attitude. I venture to suggest that she remained a drug addict throughout her treatment, and that the improvement in her condition was essentially attributable to the correction of the prolonged dietetic deficiency.

Although narcotic drug addiction is not regarded, quantitatively, as a serious problem in the United Kingdom, individual cases are most resistant to permanent cure and merit scientific attention. It is likely that addiction is the result of personality inadequacies plus the action of the drug on the tissues, the latter leading to dietetic and vitamin deficiencies. If the patient described by Comerford and Kirman was in fact "cured" of her drug addiction the value of their contribution is additionally notable on that account, and tends to confirm the advantage of combining vitamin therapy with other measures in the treatment of drug addiction.—I am, etc.,

Poona. Ellis Stungo,
Major, R.A.M.C.

Chin-Chin!

Sir,—I am glad that at last the question of overeating by our Western civilized races is now being exposed. Nearly 20 years ago an outstanding London physician found fault with my surplus weight. I asked him how I was to reduce it. He said, "Take more exercise." I do not care for violent exercise. I had occasion to take my wife to a London gynaecologist. He said she was over weight and must reduce. He said to her, "You must go on a course of thyroid." Some years later I had the good fortune to read W. J. Christie's book on *Surplus Fat and How to Reduce it*. I then discovered, to my intense surprise, that fat came from excess intake over output. My wife and I, with a little strength of will, have been able to control our weights down to reasonable proportions for the last 13 years. It has required comparatively little effort but a knowledge of the various foods which are fattening. I do not think it has required much sacrifice, because, for some unknown reason, once the weight has been reduced our metabolism seems to have altered and we are not quite so liable to put on weight, even though we do enjoy the good things of the table. When we want to reduce a little we simply eat less. When I checked back to my previous extravagances at the dining-table I found that for years I had regularly consumed, like so many of my friends, a daily allowance of 4,000 to 5,500 calories. One outstanding observation during the siege of Malta was the large number of doctors, once corpulent, who discovered that on the meagre siege ration scales their figures went right back to what they were as young medical students. It was remarkable how surprised they were that they had lost weight, and it seemed as if few realized that fat comes from food. Let any fat person count up the calories he or she has consumed regularly every day for some years back, and they will be surprised to find how much excess intake over output they have been consuming. I have never known a single person who had the necessary strength of will fail to reduce weight by eating less and eating more carefully.—I am, etc.,

"Four Chins."

Abdominal Nerve Block

Sir,—Abdominal nerve block will probably be more extensively used when the suprapubic region can be rendered insensible with greater certainty. Bishop, Carr, Anson, and Ashley (*Quarterly Bulletin, Northwestern University Medical School*, Chicago, 1943, Fall Quarter) have demonstrated the frequency of distal anastomoses between the nerves to the anterior abdominal wall. I have bilaterally dissected the thoracic XII, ilio-hypogastric, and ilio-inguinal nerves on four unpreserved subjects within 24 hours of death. In every instance the nerves had a different pattern and position, even on the two sides of the same subject.

From these observations and from practical experience I conclude that to be certain of blocking the ilio-hypogastric and ilio-inguinal nerves it is necessary to infiltrate the internal oblique muscle from 3 to 4 cm. cephalad to 2 cm. caudad to the anterior superior iliac spine in a line 2 cm. medial to the spine, and that the infiltration must be continued laterally and cephalad through the internal oblique and transversalis muscle to a distance of 3 to 4 cm. from 3 to 4 cm. cephalad to 2 to 3 cm. caudad to the iliac crest. Such an infiltration requires 20 c.cm. 1 in 200 novocain (procaine), 1 in 2000 nupercaine, or 1 in 3000 amethocaine in 0.9% saline solution.

When the correct technique has been acquired the results will be found satisfactory. Speed comes with practice.—I am, etc.,

F. R. W. Kinkead Allen.

A Coincidence?

Sir,—The following two cases should be of interest, as I can find no reference in the literature to a relationship between history of twins and dextrocardia, and these two cases suggest a genetic relationship between the two. The cases were seen within two weeks of each other and were in no way related.

Case 1.—Male aged 44. On examination the apex beat was situated on the right side of the chest in the fifth interspace, 3½ in. from the mid-line. The lungs appeared normal and liver dullness was on the left side. Clinical diagnosis of dextrocardia with reversal of viscera was made and confirmed by *x*-ray examination of the chest and barium meal. The patient gave a history that his mother and father were each one of twins.

Case 2.—Female, aged 48, with practically similar findings also confirmed by *x*-ray examination and barium meal. She gave a history that: (1) grandmother and grandfather were each one of twins; (2) sister had twins; (3) uncle had three sets of twins.

These two cases were seen during routine examinations in general practice, and on account of the rarity of the condition the possibility of further cases is remote. It is interesting to note that the man had been left-handed from birth, while the woman was normal in this respect. The relationship here between dextrocardia and twins may be purely coincidental, but it is possible that some genetic factor may be involved.—I am, etc.,

Leamington Spa. Joseph C. Joyce.

Bitterness

Sir,—I strongly suspect that the "bitterness" felt between Service and non-Service medical men is by no means one-sided. It will take all the calm reasoning of many Major Stallards to eliminate the feeling which undoubtedly exists on the side of the E.M.S. It is for us, therefore, to be tolerant and sympathetic to the resentment of those who did not go to war. The man who wanted to go and for one reason or another was not allowed to do so feels envious of his more fortunate colleagues, while the man who "dodged the column" cannot easily forgive those who come back after years of precious experience of mankind and stirring events, with the horizon of their minds widened in a way that should fortify them against any and every adversity that they may encounter in the future.

To the disgruntled Service man I would say: "Knowing what has happened (and your father would have told you exactly the same story after the last war) and if you were put back to 1939 would you have done any differently? Of course you wouldn't; because you are you and not the man next door. Well, then, don't grumble about it. Just be sorry for the man who has been deprived of these rich experiences, either by misfortune or by the narrow ambitions of his own mind."

Dr. J. M. G. Wilson (Oct. 6, p. 477) seems to be suffering from a rather pathetic inferiority complex. Any man who is not the better for his life in one of the Services must have been blind to the world in which he moved. The worst if not the only defect that one notices at the end of a Service doctor's career is a slightly reduced capacity to suffer fools gladly. No doubt even this cardinal virtue will be restored to him after a month or two of the less pressing conditions and more evolved self-discipline imposed by civilian life.

I must protest also against what Squad. Ldr. J. L. Brown has to say about "time-wasting sanitation." Most of my time has been spent in doing surgery in the forward areas of North Africa and Italy, but for three months I had to battle with the problem of keeping a meagre force of French *maquis* "in the field" (literally) and free from epidemics. This force was totally untrained in the elements of hygiene, and as short of paper as it was of soap and even water. The inculcating of a few ideas on "time-wasting sanitation" served a more useful purpose in the war effort than the exhibition of technical surgical skill on a few individuals. Moreover the emphasis in medical practice of the future is more and more in this direction.—I am, etc.,

Geoffrey E. Parker,
Millbank, S.W. Major, R.A.M.C.

An Institute of Medical Photography

Sir,—Almost twenty years of hospital clinical portrait photography of the highest quality and usefulness, carried out by my colleague Dr A. H. Turton in the skin department of the Royal Victoria and West Hants Hospital, has taught us several lessons: that the patient should be photographed promptly, when first seen, before treatment has altered appearances; that this should be done by the practitioner himself who can reach the patient wherever he is, or by the member of the hospital staff who picks out patient and posture, rather than by any layman. Delay in taking the photograph only means that likely cases will slip away, or will not be seen again in the same interesting phase of the illness. It seems unlikely that a hospital authority would interest itself, whether in the matter of money or photographer or dark-room accommodation, in what is purely a professional concern, a diagnostic refinement, well-intentioned though it might be.

Mr. H. Mandiwall suggests (Oct. 6, p. 479) that the first thing needed is a competent photographer, and he is right: this is the crux of the whole matter. The clinical photographer must be self-trained; no snapshot is good or near enough; a suitable camera with portrait lens is a necessity, and a good light with screening for background desirable. To go along with each negative and print there must be a full caption; without this the value of the picture is vastly lessened.

In time coloured photography may come into vogue; but in skin patients particularly the coloured portrait of a well-executed tinted wax cast, though taking much art and time in production, can present a life-like image. Coloured prints of static moments, or kinetograph reproductions of movements in disease, require specialized knowledge and apparatus, and cost much in time and money; in any case they have a limited use only. For demonstration purposes, though colourless, the ordinary well-taken photograph and the lantern slide prepared from the negative are of the most use to the practitioner, and the photomicrograph to the pathologist; but only if captioned amply enough.

The best service to be rendered by an institute would be as a centre for London meetings and demonstrations in clinical photography, for storage of pooled negatives and prints that over-fill shelves and cupboards; but, most important of all, to issue a monthly or quarterly photographic journal to serve a similar purpose in medical journalism as the illustrated daily does in the newspaper world; run on business lines and for members of the profession and medical libraries, exclusively. Such a journal published under the aegis of the British Medical Association—to control policy, printing, and separate sale—would serve the purpose admirably.

In the past the pictorial art has been made too little use of in medical literature and practice; nor has the profession been well served in the matter by its journals. "The pictures for the page atone"; not to take and print a good photograph is to cast a pearl away. There is a saying which has truth in it: "Better a picture than a thousand words." A photograph is the next best thing to contemplating the patient in person; besides, seeing is believing, and might spare one a little the laborious reading of wordy books and papers.—I am, etc.,

Bournemouth. S. Watson Smith.

"Reasons" for Scientific Research

Sir,—I was delighted to read the leading article on Pasteur (Sept. 29, p. 429), but two remarks need further elucidation. You ascribe the famous retort, "What is the use of a newborn baby?" to Benjamin Franklin. I have always understood it to have been uttered by Faraday when asked as to the use of his discovery of the relation between electricity and magnetism.

Your remark that there are "present-day scientists who would restrict scientific research to subjects of 'social value'" is also in need of some explaining. Who are these scientists and what is meant by "social value"? Surely all research is of value to human society, with the exception of certain researches conducted at Belsen and Buchenwald. When one discusses the value of research it is important to remember that research satisfies many values and needs, and that it is conducted for many purposes and reasons. I know of only two theories on the reasons for scientific research. One theory states that it is done solely to satisfy the curiosity of research workers and presumably those who finance them. The other states that research is of two kinds: practical and theoretical. The former is applied to problems arising out of the current practice of society; the latter kind of research is applied to the theoretical problems arising out of the practical problems and out of previous theoretical problems. Since the latter theory explains not only "why" research is done but also "what" research is done, it should be possible to decide between these theories by practical investigation. After all, human curiosity, being innate, is always the same.

I would be delighted to hear an explanation of the fact that we can spend £5,000,000,000 on the atomic bomb, while there is not even £1,000,000 a year for medical research—in terms of human curiosity and a disinterested passion for truth.—I am, etc.,

M. Hamilton, Fl. Lieut.

Press Publicity

Sir,—It is rather a fortunate coincidence that concurrent with the letters from Sir Adolphe Abrahams and Mr. John Langdon-Davies on press publicity (Sept. 29, p. 444) appears a suggestion in the *World's Press News* by Mr. W. E. Dick, the editor of *Discovery*, that there should be formed a Guild of Science Writers. He suggests that membership of the guild would require the writer to hold some scientific qualification, a token to both the newspaper and the scientific worlds of the individual writer's competence to handle scientific subjects.

As a writer for many years on medical subjects I welcome both the suggestion of Mr. Dick and the letters of Sir Adolphe Abrahams and Mr. Langdon-Davies, especially the knowledgeable remarks of the latter. The trouble is that the average journalist is practically entirely ignorant of medical knowledge; indeed he often knows less than the young first-aider. He knows nothing of medical history; Harvey to him is probably a boxing exponent; he cannot distinguish between the sulphonamides and sulphanilamide and lumps them all under M & B. The result is that when he has to cover a medical story he cannot meet the doctor or surgeon on his own ground or talk the same language, and so chooses the sensational angle from scraps that he can understand to hide his lack of knowledge. Obviously the cure for this is not the responsibility of the medical profession; it is for editors and newspaper proprietors to see that a medical or scientific journalist is on their staff or at call to cover such stories.

Mr. Langdon-Davies's remark about the voluntary hospitals and publicity is much to the point. Where voluntary hospitals issue news items it is usually done by an appeals secretary, who is very seldom a trained journalist, with the result that many a genuine story of wide appeal is overlooked or badly handled—the loss being that of the hospital concerned and the voluntary system. The solution here is for every voluntary hospital to have a journalist as its press officer, not necessarily in a paid capacity, though any hospital that paid a good journalist a small retaining fee would repay itself many times over in the course of a year.—I am, etc.,

Fleet Street, E.C.4. Norman K. Harrison.

Humanitarianism and the European Situation

Sir,—I have read with interest the letter from Lieut.-Col. Eric Townsend (Sept. 29, p. 446) regarding the present position in Europe, and I think that his suggestion about the care of European children is an excellent one, and one in which I, for my part, would be glad to assist, both as regards taking such a child and in any other way possible.—I am, etc.,

D. F. McCarthy,
Castlebar, Co. Mayo. County Medical Officer of Health.

Sir,—May I thank Lieut. Col. Townsend for writing, and you for publishing, his letter? I hope it will be the means of stimulating into action many who share his concern. It has had that effect on me, and I write to say that I will gladly take two children under the age of, say 10, as he suggests, for the period of one year, and I should prefer two German or Austrian children. I will also gladly take part in any committee or administrative work that might be necessary to give practical effect to the scheme.

I appreciate the difficulties in the way and quite see in advance arguments which may be used about the shortage of transport, the dangers from a psychological point of view of taking children away from their parents, etc. I would only suggest that there are unfortunately numberless children who have already lost their parents and their homes in Germany and elsewhere, and that it is to these children and others that we must look to safeguard the future peace of the world. Apart from the opportunity of saving them from the threat of death this coming winter, there would be the constructive opportunity of ensuring that they will be able to make the best possible contribution in the future.

As to transport, when it was a question of saving our own folk from Dunkirk we laughed at difficulties and they ceased to exist. We have only to care equally in this present desperate situation for the equivalent of the little ships and the individual homes to overcome the difficulties once more. Since Col. Townsend said that he was leaving for the Continent and had to leave the follow-up of his idea to someone else, so great is my own concern that if no one else takes the matter up may I ask that any others of your readers who are prepared to help should get into touch with me?—I am, etc.,

12, York Road, Harrogate. Kathleen Rutherford.

Alien Doctors

Sir,—There is little doubt that most of your readers have been distressed by the recent letters vilifying alien doctors. It is, I hope, not priggishness that prompts me to put in a word on the other side; certainly it seems only fair play that this should occasionally be done. Further, repetition in print does have an effect on the reader, and the effect in this case is one that promises release of nastiness.

If we are a profession of gentlemen (otherwise we are surely not a profession) then we are ashamed of these lapses into bad manners. If we still have any British courage then we fear no competition, and even look forward to a test that may be as stimulating as it should be valuable to us and the community. If we are a nation of calculating shopkeepers then we recall the profit to British medicine from the work done here by those with foreign names.

It was Rome's proud boast to be a city where no man is an alien save the barbarian and the slave. Some 800 years before Sidonius made this claim, Hippocrates said the physician "must be a gentleman in character, and being this he must be grave and kind to all."—I am, etc.,

A. C. Lendrum.

Sir,—Capt. John Nesfield (Oct. 6, p. 478), is afraid he will be out of a job when he gets back. The natural reaction is to find an outlet for this, and the most convenient scapegoat is the Jew, the favourite one in all countries, unfortunately, and in all ages. (What a wonderful role the Jews have, and why is this correspondence about alien doctors when what is meant is Jewish refugees, as most of them are Jewish?) This fear exists in spite of there being an acute shortage of doctors here, and even if all were released there would still not be enough to man the new health scheme. As to numbers, Capt. Nesfield knows as much as I do, which isn't much. But I still believe in the kindness of the average Briton. If the numbers prove to be small (and there is at least as much reason to suppose this as to accept the wildly exaggerated statements of Capt. Nesfield), then I hope that Christian conscience and innate British decency will allow them to remain. And in spite of the fact that Irishmen volunteered during the war it still remains true that Eire was neutral throughout and that Jews as a people lost more proportionately than anyone else in the war, not excluding Russia.—I am, etc.,

Loxwood, Sussex. J. Vine.

Sir,—In spite of the many letters which have appeared in the *Journal* during the past year or so on the subject of alien doctors, I have failed to find a single remark with regard to the attitude of the British public towards these foreigners. Surely the people whose health has been entrusted to the alien doctors should have a say in the matter. The fact, as stated by Capt. Nesfield, that a very large number of them "are entrenched in and around Harley Street" seems to prove that they are more liked by their British patients than by their British colleagues, or shall I say they are disliked by their colleagues for this very reason?

I wonder whether Capt. Nesfield has taken the trouble to find out for himself the exact number of alien doctors serving in the Forces to call it disproportionate. I am one of those who volunteered early in the war and was enlisted in the Pioneer Corps. Building Nissen huts, guarding petrol dumps, and the like was our service until, in 1941, we were given an opportunity of medical employment as civilians and released from the Army. If the Government had wanted to use us as medical officers they could have directed us accordingly. Let us be quite frank. Is the "great anxiety felt by members of the profession over-seas about our presence in the U.K." solely due to our professional inefficiency, and is the demand for us to leave this country essential for the well-being of the population which we tried to serve best during the war? If not, what then is the reason for the great anxiety?

I am quite aware, together with some of the "strange importations" as we were once referred to, that we shall be made superfluous when most of the British Service doctors will have been released. But I should have expected at least a more academic approach to the problem by some of our British colleagues, even though we are only temporary members of this noble profession.—I am, etc.,

Macclesfield. M. Tannenbaum, M.D.Graz.

Sir,—Capt. Nesfield has complained of alien doctors "entrenched in and around Harley Street and all over London," and says that of these a disproportionately small number have featured in the Services during the war. Capt. Nesfield overlooks the fact that only a small number of these doctors could have joined up, as only a small number of the applications for naturalization had been granted. The naturalized doctors who were fit and of military age have joined the Services. Capt. Nesfield wants the alien doctors to be turned out. I wonder if he has ever spent a thought on the question as to where they should go. He will know that most of them are of Jewish extraction and that their parents, relatives, or friends have been slaughtered in Germany. How can they live or practise there? Palestine, the land promised to them by the Balfour Declaration as a National Home, is now more closely and heavily guarded than ever against their entry.

After obtaining a British qualification these doctors have built up their practice, facing difficulties and handicaps quite unknown to their British colleagues. A large percentage of their patients are refugees, who have been attended by them before they were driven out by the Nazis. The rights of those who have fought for this country must be recognized. These rights are not endangered by the presence of a few alien doctors in the Harley Street district. These Jewish doctors are not "entrenched" here like a hostile battalion, but long to become British and to work together with their British colleagues.—I am, etc.,

Ealing, W.5. H. Lytton.

Nutritional Macrocytic Anaemia

Sir,—In the leading article in which the pathogenesis of nutritional macrocytic anaemia is discussed (Oct. 13, p. 501), you refer to the work of Moore and his colleagues showing that the macrocytic anaemia of pellagrins is apparently due to lack of an extrinsic factor normally supplied by dietary protein. It may therefore be of interest to your readers to know that recently we have found that rats on a diet of methionine develop a macrocytic anaemia characterized by changes in the peripheral blood and in the bone marrow similar to those in human nutritional macrocytic anaemia (Glynn, Himsworth, and Neuberger, *Brit. J. exp. Path.*; in press). The development of this anaemia is not prevented by large supplements of cystine or of iron.—We are, etc.,

Obituary

R. CUNYNGHAM BROWN, C.B.E., M.D.

We regret to announce that Dr. R. Cunyngham Brown, late Commissioner of the Board of Control for England and Wales, died on Oct. 7 in retirement at Lymington, Hants.

Robert Cunyngham Brown was born in 1867, second son of the Rev. Robert Brown, of Paisley. He was educated at the Universities of Glasgow, Durham, and Frankfurt, graduating M.B., B.S. of Durham in 1890, and M.D. in 1898. After holding several resident hospital posts and three years in general practice, he worked under Carl Weigert in his neuropathological laboratory at Frankfurt a.M. This was followed by a year and a half at the National Hospital for the Paralysed and Epileptic, London, and a period as pathologist to the County Asylum, Chester. In 1899 Cunyngham Brown entered the Prison Service as deputy medical officer, and twelve years later was transferred to Scotland as Deputy Commissioner in Lunacy. In 1915 he was seconded to the R.A.M.C. with the temporary rank of major, and held the post of officer-in-charge of Strongburn-Woodside Military Hospital, Glasgow; he then went over-seas for service in Macedonia with the 37th British Hospital attached to the Serbian Army and as mental specialist to the Salonika Command. He was recalled to England and lent to the Ministry of National Service, and in 1919 was officially transferred to the Ministry of Pensions as Deputy Director-General of Medical Services, retiring in 1925. For the next six years he was a Commissioner at the Board of Control. His services in the war of 1914–18 were recognized by decorations from the Portuguese and Serbian Governments, and he was mentioned in dispatches.

Cunyngham Brown was an able and fluent writer, and everything he wrote or said or did bore the mark of enthusiasm and good will. He was joint author of a paper on diffuse encephalitis in *Brain* in 1892, wrote two clinical papers for the *Lancet*, and an article on the boarding-out of the insane in private dwellings for the *Journal of Mental Science*; he also prepared a report on the family care of the insane poor for the Royal Commission on the Care and Control of the Feeble-minded. He was a valued contributor to these columns for some years, and his occasional visits to the editorial office made one feel that a breath of genial sea air had come to London.

Dr. Alfred Cox writes:

Cunyngham Brown has been a friend of mine for nearly 60 years, though we met rarely. He was fellow student of mine at Newcastle-upon-Tyne and one of the most popular men in college. He had many advantages—he was a son of the manse, he had a good brain, a handsome and imposing presence, and a sweetness and generosity of disposition which characterized him all his life. In spite of the important official positions he held, always with credit and distinction, Brown was never much in the limelight. He went about the world a good deal on official missions and generally turned up at B.M.A. headquarters to report himself to me and the Editor. He was a favourite with everybody who knew him, and he had the happy family life he deserved until two of his sons failed to get away from Malaya when the Japs invaded it. I had heard nothing of him since I was told that he and his wife were going East to look for them. I hope he was successful. His heart was as big as his body, and that is saying much.

K. W. M. writes:

Robert Cunyngham Brown numbered Dr. John Brown of *Rab and his Friends* among his forebears, and on his mother's side was a Shetlander. After a medical course in the Universities of Durham and Glasgow he went to Frankfort to study neurology, and on returning to Great Britain was appointed a clinical assistant at the Queen's Square Hospital, where he made a special study of tabes dorsalis. He went then into the Prison Medical Service, and in more than one institution was responsible for improvements in the treatment of inmates, more particularly in the provision of reasonable occupation and opportunities for education. His work in this respect left its mark on the whole prison service. He left H.M. Prison, Birmingham, in 1912 to become Deputy Commissioner in Lunacy for Scotland.

On the outbreak of war in 1914 he applied for military service, and was put in charge of Woodside and Springburn Military Hospitals, Glasgow. Thence he went in May, 1916, as captain, R.A.M.C., to Macedonia with the 37th General Hospital attached to the 1st Serbian Army; and after acting later as consultant in mental disease to the Salonika Command was recalled in 1918 to join the staff of the Ministry of National Service. He was transferred in this year to the Ministry of Pensions, where he filled the office of Deputy Director-General of Medical Services. His experience as a civil servant stood him in good stead in this important post, and it was due to his advice on policy that the system of Pensions Boards and other complicated machinery for dealing fairly with the returned soldier were set up. Ill-health traceable to severe dysentery in Macedonia compelled his retirement from the Ministry of Pensions in 1925, but he surprised his friends by a complete recovery, and was appointed a Commissioner on the Board of Control for England and Wales in 1927. He served in this office until his final retirement in 1933.

During the earlier part of his professional career he published several papers of recognized importance on neurological subjects; later he did much reviewing and article-writing for medical journals, particularly for the *British Medical Journal*, with whose late Editor, Sir Dawson Williams, he enjoyed a close friendship. In the various services to which he was attached—the Prison Medical Service, the Ministry of Pensions, and on the Board of Control—his influence was great and abiding, owing first to a far-reaching intelligence which enabled him to see the implications of problems, and particularly their implications for persons—for the prisoner, the pensioner, and the mentally afflicted—but above all to the complete integrity of his character. As to the latter, it is difficult to speak plainly. The more intimate his friends, the more they came to grasp his complete selflessness in every relationship into which he was brought by his work and by the other occupations of every day. He was repaid by the deep affection of many, the only coin which he valued, though it is certain that he never counted what was given him. During the last year he had to bear the affliction of almost total blindness from glaucoma, and a few days before his death he heard of that of his second son on the Bankok–Moulmein railway in 1943; but almost at the same time he also heard of the safety of his third son in Singapore, whose fate had been unknown since February, 1942. His wife, a daughter, and his third son survive him. A distinguished public servant, a great doctor, and a splendid friend.

A. S. writes:

The words "a great gentleman" are not lightly to be used, but none who knew "C. B." would question his possession of all that they imply. Tall, handsome, debonair, his physical presence impressed, whilst his voice and greeting showed an immediate personal interest, whoever you might be. This initial charm did not fade as one came to know him better; it was a true expression of the man. He could indeed be sharp and peremptory if need be; he could be unreasonable or inconsequential, but he was never small-minded or self-seeking. He believed the best of his fellow-men, and evoked the best from them.

As Deputy to the Director-General of Medical Services of the Ministry of Pensions, Sir Lisle Webb (whose death has strangely occurred on the same day), he was a loyal, strong support through the difficulties of the early post-war years, and his wide experience of mental and allied diseases was invaluable in solving many clinical and administrative problems. By his colleagues, medical and lay, he was beloved. An endearing trait was an absent-mindedness which lost him countless umbrellas, and once, it is said, while visiting an office at Northampton he suddenly remembered it was Southampton to which he had set out.

For health reasons, fortunately temporary, he retired from the Ministry after only six years' service; but, though the loss was great, his influence remained. During the late war he returned as a specialist on medical boards; as keen, as energetic, as courteous as ever, bearing heavy domestic anxieties and sorrows with a smiling fortitude.

JOHN WOOD, M.B., Ch.B., D.T.M.

The sudden, unexpected death of Dr. John Wood of Bournemouth has brought much sorrow to all who knew him as physician and friend. Born in Aberdeen in 1890, he was educated at Gordon's College there, afterwards at the University, where in 1912 he graduated in medicine. From the first his intention had been to educate himself for work in the foreign mission field. With this end in view, immediately on qualifying he became house-surgeon at the Worcester Royal Infirmary; later he proceeded to take the D.T.M. at Liverpool (1915) in preparation for medical missionary work under the aegis of the Church of Scotland. After ordination he was directed to Calabar, Southern Nigeria, West Africa, for duty and in charge of the Mary Slessor Hospital at Ztu on the Cross River and of eleven widely scattered mission stations based on the hospital. After some time there he was transferred to a newly built hospital and mission station at Uburu, where he continued to do valuable pioneer work. Being young, keen, active, and conscientious, John Wood speedily mastered the local dialects and made his work indispensable; he was held in high esteem by the natives among whom he ministered. In the end his health and his wife's health suffered so severely by reason of the death-dealing environment in which they lived and worked, and by the poor sustenance that the country afforded, that both were ordered home for good.

John Wood, on his return, settled in practice at Wigan, being appointed assistant surgeon to Wigan Royal Infirmary and medical officer and vaccinator to Wigan Union. After five strenuous years, for health reasons, he relinquished practice there and settled in Bournemouth, where he continued to live and work for his remaining years; by his gentleness, his sympathetic kindness, and his conscientiousness endearing himself to all who came into contact with him. It was the divine side in John Wood that brought him of his own free will to sacrifice himself for others by accepting missionary work, and in the parasite-infested wilds of West Africa. In all he did he seemed to be guided by an abiding faith to support in him a matchless fortitude and determination in a nature both kind and gentle. Constantly, in all manner of ways, he strove to do good and to help and encourage others, with never a thought of self. There were in him all the fine qualities of the stock from which he came: all the virtues went to build in him that nobility of character we knew to be his. Near the surface, often breaking out unexpectedly, lay a pawky, dry humour that was characteristically Scottish. He possessed the quiet, tranquil mind along with a becoming humility, owning all the attractive attributes with which Newman endowed the true gentleman. Of all men, John Wood could claim to say, "I have fought the good fight, I have finished the course, I have kept the faith." Much sympathy will be felt for his widow and five children in their grievous loss. S. W. S.

We regret to announce that Dr. Robert Edward Burnet Yelf, formerly of Moreton-in-Marsh, Gloucestershire, died in hospital at Chichester on Sept. 25. Born at Moreton on May 12, 1866, the son of a medical man, he was educated at Chipping Campden Grammar School and the University of Edinburgh, where he graduated M.B., C.M. in 1888. Dr. Yelf was for many years surgeon to the Moreton Cottage Hospital and district M.O. for the Shipston-on-Stour Union, and M.O.H. for Stow-on-the-Wold Rural District Council. During part of the war of 1914–18 he served as temporary lieutenant, R.A.M.C. He joined the B.M.A. immediately after graduation, was chairman of the Oxford Division and president of the Oxford and Reading Branch in 1908, and was made an Associate Member of the Oxford Division in 1931 when he left Moreton-in-Marsh to live at Selsey. In Moreton and for a wide radius around he had identified himself with every aspect of local life. On his departure a presentation, subscribed to by 730 people, was made to Dr. and Mrs. Yelf to mark the affection and esteem in which they were held. His father, whom he joined in practice in 1888 and succeeded in 1895, was one of the founders of the cottage hospital. In his younger days Dr. R. E. B. Yelf was a keen sportsman and captain of the local cricket and football teams. He had been for many years honorary secretary of the Moreton working men's club, chairman of the parish council, and at one time captain of the fire brigade. After leaving the Cotswolds for Selsey he became an active member of the bowling and tennis club, and did much to maintain the greens and courts when the regular staff were away. During the war, though retired from active practice, Dr. Yelf took on a great deal of medical work once more in order to replace the younger medical men who had joined the Forces, and up to the time of the short illness which preceded his death he was working in the village among his numerous patients, with a cheery smile and a word for everyone he passed on the road.

The Services

Surg. Capt. F. L. Cassidi, V.D., R.N.V.R., has been appointed an Honorary Surgeon to the King.

Surg. Cmdrs. E. C. Johnson, A. L. Gunn, and G. P. McCullagh have been awarded the R.N.V.R. Officers' Decoration.

Acting Group Capt. Sir Louis L. Greig, K.B.E., C.V.O., R.A.F., has been appointed an Officer of the Legion of Merit by the President of the U.S.A.

Acting Surg. Lieut.-Cmdr. J. S. Guest, R.A.N.R., has been appointed O.B.E. (Military Division) for great skill and devotion to duty as Principal Medical Officer of H.M.A.S. *Westralia* during the landing on Tarakan Island on May 1.

Surg. Lieut.-Cmdr. W. H. Milroy, R.A.N.R., has been mentioned in dispatches for skilful organization and for courage and devotion to duty in the operations covering the assault landing of 2/48th Assault Battalion, 9th Australian Division, at Tarakan on May 1, while serving in one of H.M. Australian ships.

The following appointments, awards, and mentions in dispatches have been announced in recognition of gallant and distinguished services in the field:

M.B.E. (Military Division).—Lieut.-Col. (Acting) W. E. A. Buchanan, T.D., Lieut.-Col. (Temp.) J. C. Mackay, M.C., T.D., Major W. L. Kinnear, and Major (Acting) J. D. Finlayson, R.A.M.C.

M.C.—Capt. J. Burns and Lieuts. R. Mackay, D. J. Macrae, F. W. M. Plant, and G. E. Stoker, R.A.M.C.

Mentioned in Dispatches.—Major (Temp.) C. H. Imrie, Capt. J. Morrissey (killed in action), Capt. (Temp.) A. Taylor-Smith, and Lieut. G. H. Darke, R.A.M.C.

Freed in the Far East.—Lieut.-Cols. H. C. Benson and C. W. Maisey, Major P. B. Hanbury, Capts. A. Barber, G. Blair, A. W. Frankland, D. W. F. Gotla, and V. W. J. Hetreed, R.A.M.C.; Major S. C. Colbeck, I.M.S.; Surg. Lieut. D. R. Syred, R.N.V.R.; Fl. Lieut. R. F. Braithwaite, R.A.F.V.R.

Repatriated.—Col. Julian Taylor, A.M.S.

CASUALTIES IN THE MEDICAL SERVICES

Killed.—Capt. Jacob Hyman Joseph, R.A.M.C.

Died.—Major Campbell William Kidson and War Subs. Capt. Denis John Burgess, R.A.M.C.

Died at sea while on active service.—Major Vivian Roy Clifton, R.A.M.C.

Wounded.—War Subs. Capts. J. G. A. Gilruth and J. A. Perpoli, M.C., and Temp. Lieut.-Col. J. M. Scott, R.A.M.C.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

The *Cambridge University Reporter* dated Oct. 9 contains a copy of the letter from the Home Office informing the Vice-Chancellor that the King by Letters Patent under the Great Seal bearing date Sept. 1 appointed Sir Lionel E. H. Whitby, C.V.O., M.D., F.R.C.P., to be Regius Professor of Physic in the University. The *Reporter* also prints the full text of the address to the Senate given in Congregation on Oct. 1 by Dr. T. S. Hele, Master of Emmanuel College, on resigning the office of Vice-Chancellor. Speaking of medical events of the past year Dr. Hele recalled that through the kind offices of the Medical Research Council a Chair of Experimental Medicine had been established for Dr. R. A. McCance, whose department is receiving further assistance from the same source. Addenbrooke's Hospital and the University were collaborating closely in the development of the School of Clinical Research. In the Shire Hall under Dr. Robert Ellis, chairman of the Cambridgeshire County Council, the future of the medical services of the area had been discussed by representatives of local authorities and hospitals, with representatives of the University present on these occasions. For the next five years the difficulties arising out of the enforced use of temporary and inadequate accommodation for the hospital services of the area would delay the full development of the School and of the ancillary services which the University would help to provide for the maintenance of health and for the diagnosis and treatment of disease. "Our guests—should I say paying guests?—from other Universities with one exception have departed, taking with them our very best wishes for the re-establishment of their work at home, and with grateful acknowledgment of the mutual help and inspiration which their presence in Cambridge during six critical years has engendered. St. Bartholomew's Hospital Medical School will return to their premises in Charterhouse Square when sufficient repairs have been completed."

Titles of the degrees of M.B., B.Chir. were conferred by diploma during the months of July, August, and September, 1945, on J. S. Keilin and C. N. Smith, of Girton College, and on I. M. S. Chappel, P. J. Coope, M. E. P. Hele, L. A. Norris, H. M. Russell, J. Whitham, and G. B. Wrong, of Newnham College.

Names of candidates for the M.Chir. examination should be sent to the Registrary by Jan. 1, 1946; the examination begins on Feb. 19.

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

At a meeting of the Council, held on Oct. 6 in the College House, with the President, Mr. Eardley Holland, in the chair, the following were admitted to the Membership: T. S. M. Barnett, A. Buchan, Daphne W. C. Chun, Aileen M. Dickins, E. D. Y. Grasby, M. W. Hemans, Ursula M. Lister, Agnes M. D. Milne, Abd El-S. M. El-Minabbawy, K. Mitra, Joan P. Moignard, P. Raj, W. B. Shute, Beatrice M. Smyth, J. M. Thomson.

Medical Notes in Parliament

Industrial Injuries Insurance

Mr. James Griffiths moved the Second Reading of the National Insurance (Industrial Injuries) Bill. He said that of the four measures needed to give effect to the White Paper scheme for a comprehensive system of social insurance two had passed into law. The first set up the Ministry of National Insurance. The second was the Family Allowances Act. This Bill was far more involved than either. The fourth would be even more complicated than the third, the present Bill. The broad principles on which the scheme of industrial injuries insurance was based had been outlined in the White Paper on Social Insurance. In accordance with this the Bill was to make compensation for industrial injuries a part of the country's social services and to make these injuries a matter for settlement on the basis of fixed benefits to be paid for a fixed premium. The Bill would be the end of "compounding." All persons employed in Great Britain under any contract of service or apprenticeship would be insurable without any income limit. Certain other people were being brought in—for example, members of lifeboat crews, employees of any local or public authority, taxi drivers, and members of rescue and fire parties in mines and works. Seamen and other persons employed for the purpose of the vessel or of the cargo or of passengers on British and British-owned ships, and civilian airmen employed on British aircraft were covered. Criticisms of the present Acts on the ground that the onus of proof always rested on the worker had been met by addition of a proviso that, for the purposes of this Act, an accident arising in the course of an insured person's employment should be deemed, in the absence of evidence to the contrary, also to have arisen out of that employment.

Expounding the details of the Bill, Mr. Griffiths said that, where at the end of an injury benefit period an injured man still suffered from disablement which was likely to be permanent or was substantial, he would be assessed for pension. This would be awarded in proportion to his loss of health, strength, and power to enjoy life. It would be awarded irrespective of his earnings. The disabilities which were to be regarded as attracting a pension of 100% were to be prescribed later. If a pensioner had to enter hospital for further treatment on account of his injury he would, so long as he was in hospital, receive pension at the full 100% rate irrespective of his normal assessment, but subject to a reduction of 10s. a week in respect of home savings. To-day a man could not draw sickness benefit and workman's compensation for the same injury. The Government had decided to modify that. Under its scheme a pensioner who was unfit for work would be entitled to sickness benefit even when his unfitness was due to his injury, subject to the provision that, if his pension was at the 100% rate, sickness benefit would be at half rate until he had paid ten contributions since the date of his accident. All benefit rates were on an equality for both men and women. As this was a State system of insurance, claims would be decided by officers appointed by the Minister to be insurance officers. Independent local appeal tribunals would hear and decide appeals from the insurance officers' decisions. There would be a final appeal to a Commissioner who would be a legal expert appointed by the Crown. The Bill contained a provision for financial aid to be given to persons engaged on research into the causes and prevention of industrial accidents and disease and for the Minister himself to employ persons to carry out such research. There was also a provision enabling the Minister to provide artificial limbs and other appliances to pensioners either free or at reduced rates. There was to be appointed an Industrial Injuries Advisory Council to which he would ask employers' and workers' organizations to nominate members. To the injured man the cash payments were not the most important thing: The most important thing was that he should be fitted for a new life. That was where the old system failed completely.

DEBATE ON THE BILL

Mr. OSBERT PEAKE said one of the great merits of the new scheme was that by a new method of assessing disability it provided a firm basis of supplementary schemes. There must be a close link with the new health and hospital services of the Ministry of Health and with the rehabilitating and retraining services of the Ministry of Labour. Miss BACON hoped the equipment provided would include invalid chairs and spinal carriages. The cost of these was beyond the capacity of injured workmen to pay. Mr. CLEMENT DAVIES spoke of the conditions in the quarrying industry of North Wales in galleries where the candle would not remain alight when it was standing up. The men worked in such conditions of dust that they could not be seen by men within two yards of them. Yet that type of workman was outside the scope of the Workmen's Compensation Acts. He asked why the small employer who had only one employee was outside the scope of the Act. With a broader measure there would be no legal question but only a medical question, with the medical man saying that a person was fit or unfit and what assistance he would require to rehabilitate himself.

Mr. CLITHEROW said that he himself was a final-year medical student. He asked the Minister to insert words so that the Bill should include health workers who contracted tuberculosis through being directly in contact with tuberculous patients in the course of their normal duties, or within a reasonable time afterwards. He suggested this because of his own observations both as a medical student and as a member of the Liverpool City Council sitting on the Hospitals' Committee. Nurses and health workers and the medical profession themselves had a thorough medical examination before they started. At their first start they were far healthier than the average. He gave instances of medical students who had fallen ill with tuberculosis. His observations were that one in every fifty medical students went down with tuberculosis during the three years of clinical work. It was distressing to see the number of nurses whose names appeared before the Liverpool Corporation Hospitals' Committee as having gone down with colds, and eventually with tuberculosis. The committee paid them a full salary for about three months, half salary for a further three months, and then cast them off like an old glove. Counsel's opinion had been that tuberculosis was not an industrial disease. Even if a girl could prove that a patient with an active lesion coughed in her face, and that pulmonary tuberculosis could be attributed to it, that was deemed to be an accident. He hoped that in the Committee stage an amendment would be made to include these girls.

Dr. STEPHEN TAYLOR said the Bill got rid of the endless legal and medical wrangles which had wasted so much money, but it perpetuated the distinction between industrial injury and non-industrial injury and disease. He hoped the Minister would assure the House that all nurses would be covered in the Bill, particularly those working on private nursing. With every safeguard the nurse was liable to septic fingers, kidney infections, and septicaemia. Regular x-ray tests, Mantoux tests, and blood counts were not done. Admittedly, in good sanatoria the nurses were not more liable to tuberculosis than the rest of the community, but he was pretty sure that taking the nursing profession as a whole they were more liable. The ills of nursing were not in the Schedule of Industrial Diseases. In the past, trade unions had to waste their energy getting diseases scheduled when that energy should have been used in getting rid of the diseases. Research workers spent their time proving a connexion between the disease and the occupation instead of trying to get rid of the disease. The Bill gave the Minister power to promote and assist research into the causes, incidence, and methods of prevention of industrial disease. He hoped that to this the Minister would add research into the treatment of industrial accidents and diseases, because this treatment was still far from perfect. Good work had been done in this field by the Industrial Health Research Board. He trusted the Minister would use the Board and the Medical Research Council, and would strike out on his own in the research field. He must provide his research workers generously with field workers, clerical staff, and laboratory technicians. Mental disability made up a large part of industrial disability. He hoped the Minister would generously promote research into industrial psychiatry and on the measurement of fatigue, of accident-proneness, and so on, and that he would encourage the work of those psychiatrists who had been busy in the Army. They should help the industrial neurotics over their stiles.

Mr. DAVID WILLIAMS spoke on silicosis and pneumoconiosis. This existed on a staggering scale in West Wales, where one colliery from Jan. 1 to Sept. 29, 1945, had lost 200 men—more than one in eight. Once a man was certified to be partially or totally disabled with these diseases he did not return to the mining industry, so that 20% disability in such cases caused greater hardship than 20% physical disability resulting from accident.

Dr. H. B. MORGAN said that in some workshops new organic solvents were being used upon which practically no research had been made. In some of the finest factories in Great Britain solvents were in use which the workman was forced to inhale, and which in three months would give him anaemia, from which he would never recover. He asked whether it was true that in Wales and the North-West the number of cases awaiting decision by the Silicosis Boards were two years in arrears. Was it true that the Government was doing practically nothing to train doctors for those positions?

REPLY FOR THE GOVERNMENT

Mr. LINDGREN, replying for the Government, said the Minister desired that the provision of artificial limbs and surgical appliances should include wheeled chairs, spinal carriages, and equipment necessary for sick-rooms and for the treatment of a patient whilst bed-ridden at home. Referring to the plea of Mr. Clitherow for the inclusion of nurses and health workers in regard to consumption and other diseases arising from their work in hospitals, Mr. Lindgren said there were great difficulties in making provision for health workers within workmen's compensation measures because of the incidence of the diseases with which these workers dealt, and because of lack of proof that diseases arose out of or in the course of their employment. The Minister would desire, if possible, to provide for the workers and would like to have discussions between the Ministry of Health, the Ministry of National Insurance, and those who could speak on behalf of persons engaged on such work to see whether it was possible to bring them in.

The debate was adjourned until Oct. 11, when after further discussion the Bill was read a second time and was sent to a Standing Committee.

Medical Officers in the B.L.A.

In a reply to Sir John Mellor Mr. BEVAN agreed that in August the B.L.A. had one medical officer for 409 officers and other ranks compared with one general practitioner for 2,576 civilians in the United Kingdom. He added that the civilian position could be remedied only by acceleration in the rate at which doctors were released from the Services. The Government was urgently considering to what extent this was practicable.

Compensation for Medical Practices

Mr. YORK on Oct. 11 asked the Minister of Health to state the intentions of the Government in regard to compensation for medical practices if taken over under the National Health Service. He also pressed for a general statement in regard to medical practices, in order that demobilized doctors may decide whether to purchase practices.

Mr. BEVAN said that he had this matter under immediate review. He was not yet ready to make any statement, but knew the urgency and would do so as soon as he could.

Experimental Health Centres

Mr. DUMPLETON suggested on Oct. 11 that the Minister of Health, pending the establishment of a National Health Service, should initiate experimental health centres in suitable places.

Mr. BEVAN did not think it would be practicable to make this provision in advance of the new legislation. He added he was pressing on rapidly with the preparation of the Health Services Bill, which would deal fully with the subject.

Working Conditions for Nurses

Mr. DUMPLETON asked on Oct. 11 what steps the Minister of Health proposed to take to improve the bad working conditions and hours of nurses in hospitals and institutions.

Mr. BEVAN did not accept the implication that bad working conditions for nurses in hospitals and institutions were general. Where they existed they were in large part due to the effects of the war. He was giving this matter most earnest consideration in consultation with Mr. Isaacs and with the bodies principally concerned. He hoped to make a full statement within the next few weeks.

Release of N. Ireland Doctors.—Dr. LITTLE on Oct. 11 urged the Minister of Health, in view of the shortage of doctors in Northern Ireland, to release at the earliest moment doctors who volunteered their services for the duration of the war. Mr. BEVAN replied that the question of the acceleration of the release of doctors from the Services is at present under urgent consideration.

Medical News

A meeting of the Medico-Legal Society will be held at 26, Portland Place, W., on Thursday, Oct. 25, at 8.15 p.m., when Dr. W. Norwood East will deliver his presidential address on "Society and the Criminal."

The programme for the annual meeting of the British Orthopaedic Association to be held at the Royal College of Surgeons, Lincoln's Inn Fields, on Oct. 26 and 27, includes the presidential address by Mr. St. J. D. Buxton on prevention of accident and limitation of injury, a symposium on some methods of treatment of simple extra-articular fractures of the femur, and a lecture and demonstration on clinical photography. The papers are as follows: Prof. T. P. McMurray, Thomas and his splint; Mr. C. H. Cullen, infection of gunshot wounds with actinomyces; Prof. H. J. Seddon, another island epidemic of poliomyelitis; Prof. J. Leveuf, primitive congenital subluxation of the hip; Mr. J. S. Batchelor, congenital dislocation of the hip; Mr. E. W. Bintcliffe, pollicization of the index finger for traumatic amputation of the thumb; Squad. Ldr. E. Somerville, air arthrography of the knee-joint; and Prof. H. Platt, the place of orthopaedics in medical education and in the regional hospital service. The Association will hold its annual dinner in the Hall of Lincoln's Inn on Friday, Oct. 26, at 7 p.m.

The annual general meeting of the London Association of the Medical Women's Federation will be held at B.M.A. House, Tavistock Square, W.C., on Friday, Oct. 26, at 8.30 p.m., when Dr. Beryl Harding will deliver her presidential address on "Relief Work in Greece."

The first meeting of European pharmacists since the war is being held in London next month on the invitation of the Pharmaceutical Society of Great Britain. The members of the Bureau of the Fédération Internationale Pharmaceutique who will attend are: Dr. E. Höst Madsen, Copenhagen, president; Mr. E. Saville Peck, M.A., Cambridge, vice-president; Prof. D. Van Os, Groningen, Holland, vice-president; Dr. T. Potjewijd, Winschoten, Holland, secretary; and M. C. Moyens, Brussels, assistant secretary.

Dr. Elsie Violet Crowe, F.R.C.S.Ed., has been released from internment in Japanese hands.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* only two diseases had totals that differed appreciably from the previous week's return—scarlet fever with 148 more notifications, and whooping-cough with 173 fewer.

A slight rise in the incidence of scarlet fever was fairly general throughout the country; the largest local rises were Yorkshire 33, and Lancashire 25. The drop in the incidence of whooping-cough was due to the experience of a few counties; the largest falls were London 38, Middlesex 34, Warwickshire 33. Although there were only 10 fewer notifications of diphtheria than in the preceding week, there were wide variations within the counties. There were fewer notifications in Lancashire by 28, and in Durham by 23, but the total for London, Middlesex, and Essex was 29 in excess of the previous week's, and reached the highest level recorded this year. The other notable increase in diphtheria was in Glamorganshire, 16.

There were 6 fewer notifications of dysentery. Relatively large local outbreaks were recorded in Dorset, Poole M.B. 18; Yorks North Riding, Middlesbrough C.B. 18; Somerset, Taunton R.D. 14. The other large returns were in London 52, Lancashire 30, Surrey 20, Essex 16, and in Suffolk 15.

In *Scotland* the chief feature of the returns was a decrease of 33 in the incidence of dysentery; this fall was general except in Glasgow, where there was a slight rise from 55 to 57. The only change in the trends of diphtheria was a rise of 7 in Glasgow.

In *Eire* the number of cases of diphtheria fell by 8, and that for whooping-cough by 26, while rises were recorded for scarlet fever 13, and measles 8. Notifications of enteritis and diarrhoea increased by 9 cases to 110, of which 84 were recorded in Dublin C.B.

In *Northern Ireland* there was a further small rise in the incidence of scarlet fever; 17 of the 42 cases were notified in Belfast C.B.

Week Ending October 6

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,683, whooping-cough 909, diphtheria 479, measles 367, acute pneumonia 377, cerebrospinal fever 38, acute poliomyelitis 29, dysentery 207, paratyphoid 11, typhoid 15.

No. 39

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Sept. 29.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1945					1944 (Corresponding Week)

---

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to movements of population, birth and death rates for Northern Ireland are still not available.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Aitiology Westcent, London.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London.*

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Westcent, London.*

ANY QUESTIONS?

Gymnastics for Young Children

Q.—*At what age should a child undertake gymnastics at school? Is there any truth in the idea that this form of activity has a harmful effect on a young child?*

A.—Gymnastics—by which term should be understood systematic activities—adapted to the age and physical capabilities of the pupils concerned form an integral part of the physical education scheme in all types of schools. Gymnastics include free and informal movements—e.g., those of a game-like character—as well as a wide range of free-standing exercises, and exercises on selected apparatus, carried out in accordance with a predetermined pattern and designed to aid healthy growth and development. Educational gymnastics have nothing in common with the type of work performed on horizontal and parallel bars, and popularly referred to as "German gymnastics."

Gymnastics can be safely and beneficially taught to the youngest pupils, though in the early age groups they appropriately take the form largely of play movements, utilized and controlled in such a way as to add to the value and enjoyment of these movements, while at the same time training the body and mind to respond to external suggestions and stimuli. They thus lead up to the immediate and more accurate physical and mental response expected from older children. Moreover, the youngest pupils, under a suitably trained teacher, can derive pleasure and profit from such basal movements as hanging, swinging, and climbing on apparatus devised for the purpose.

Gymnastics, interpreted as described above, can have no harmful effect on young children; on the contrary, they can contribute powerfully, under competent direction, to health and happiness.

Putrefaction of Meat, Poultry, and Game

Q.—*Before the discovery of penicillin it was common knowledge that putrid cheese could be eaten with impunity. The same applies to putrid game, such as grouse and partridge, while ordinary meat or poultry could not be eaten in the same stage without danger. It has often struck me that there must be something inimical to ordinary putrefactive bacteria in the decomposition of game. What are the organisms concerned in the putrefaction of game? Has the question of its possible bactericidal or bacteriostatic effect ever been investigated?*

A.—The inquirer poses a question, but also makes statements which are not altogether accurate. Putrefaction is a complicated process due to the action of many bacteria, some of which are aerobic organisms, but the main activities are due to putrefactive anaerobes. None of these organisms is pathogenic to man, and there is no evidence that the consumption of food—whether it is meat, game, poultry, or cheese—in a state of early decomposition is harmful to man, provided no pathogenic organisms are present in addition. The putrefactive changes develop rather differently in the types of food mentioned, due partly to differences in composition, including their water content, but these changes are all of the same order and due to non-pathogenic bacteria. The suggestion made that meat is dangerous if it shows putrefactive changes is still widely believed on the basis of the old idea that food-poisoning is due to ptomaines, but the conception of ptomaine poisoning is completely exploded. (See *Journal*, Jan. 6, 1945, p. 32.)

It is true that meat which is showing even incipient decomposition changes is condemned, but this action is based on the fact that the animals which supply the meat are liable to be infected with *Salmonella* and other pathogenic bacteria associated with food-poisoning, and it is a reasonable assumption that if meat exhibits such changes it has been badly looked after and that, if pathogenic organisms were present, they would have opportunities to multiply and generally infect the meat. With game and poultry the risk is slight, but here again the *sale* of such food showing decomposition changes would not be permitted.

These considerations suggest no reason to suppose that there are any substances in game which are deterrent to bacterial growth, as all the facts are fully explainable on other grounds.

Capillary Naevus

Q.—*Is a capillary naevus due to some intra-uterine arrest of development, or is it a hereditary recessive Mendelian characteristic? If both parents have naevi, are the children likely to be free?*

A.—This is certainly not a recessive Mendelian characteristic. In fact the indications for any hereditary basis are very slight. On general principles it might be anticipated, perhaps, that a general tendency to the formation of such naevi was heritable; but it is likely that non-genetic accidents of development are much more important than any such hereditary tendency in determining the actual appearance of a port-wine mark. It has been noted that the naevus often has a segmental distribution, and it may be secondary to some abnormality of the nervous system. So far as present knowledge extends, it seems probable that the child of two affected parents would run little more risk of being similarly affected than any random unselected child in the general population.

Vitamin B in General Therapy

Q.—*Could you please give a concise account of the indications, and if possible the rationale, for vitamin B therapy, which seems to be prescribed for so many varied complaints? I am not including deficiency diseases.*

A.—Vitamins of the B group may be used rationally in treatment of conditions (as distinct from frank deficiency disease) which are known to be caused in human beings by deficiency of these vitamins. For example:

Vitamin B_1 (Aneurin).—Anorexia, constipation, tingling of hands and feet, aching muscles (especially calf muscles); changes of temperament (which may be called neurasthenic), bilateral neuritis, oedema and tachycardia without obvious cardiac lesions.

Niacine (Nicotinic Acid or Nicotinamide).—Diarrhoea, changes of temperament such as morbid anxiety or fear, stomatitis (including Vincent's infection).

Riboflavin.—Corneal vascularization. Wills has shown that a nutritional macrocytic anaemia is cured by crude liver extract or marmite, but not by the purified extrinsic or intrinsic factors, nor any of the known components of the B complex. Vitamins should be given whenever the diets used in treatment are likely to be deficient—for example, when febrile patients are given large doses of glucose.

These vitamins may be used to treat conditions which are considered to resemble those that occur in deficiencies in animals. Aneurin has been used in treatment of Wernicke's syndrome on the ground that haemorrhagic lesions in the basal ganglion and brain-stem occur in pigeons on a diet deficient in aneurin. However, Joliffe *et al.* reported a large series of cases of "nicotinic acid deficiency encephalopathy" which resembled Wernicke's syndrome in their clinical picture. Joliffe found that aneurin had no effect in these cases and that nicotinic acid caused rapid improvement.

Choline and vitamins of the B group protect animals against liver damage; hence choline and concentrates of the B group have been used in treatment of cirrhosis of the liver, and good results have been claimed. On the ground of its vasodilator action, nicotinic acid has been used in treatment of Ménière's syndrome.

There is no evidence that these vitamins will benefit patients with gastric ulcer if their diet is not inadequate. Their use for various neurological conditions is based on the belief that they have some general "protective" action on the nervous system.

Vitamins of the B group are employed extensively on the ground that they may do good and can do no harm. This may be justifiable; however, recent studies suggest that the administration of large doses of a single vitamin may provoke deficiency of another vitamin. If these vitamins are given, concentrates containing all the possible members should be used.

Variations in Pulse Rate

Q.—*A man aged 60, past history no serious illnesses other than two periods of low blood pressure which were corrected with rest and treatment. Present condition: heart clinically and electrocardiographically normal. B.P. 148/88. Pulse rate varies between 60 and 40 beats a minute. What is the reason for this, and what treatment might be tried?*

A.—Variations in the pulse rate between 40 and 60 a minute may be due to a high vagal tone—that is, presuming that the pulse rate is really the heart rate and that no beats occur at the heart which do not reach the pulse. The normal electrocardiogram has excluded complete heart-block. It is not clear whether the patient feels at his worst when the pulse is slow or quick. If vagal influence is to be got rid of, then full doses of atropine in some form should be made use of. If such variations in rate are the only abnormality to be detected in the heart, then one need not restrict activity; probably exercise would improve the patient. It would be worth while knowing whether the blood pressure varied with the rate of the heart. It might be well to try full doses of strychnine, or some stimulant of the sympathetic such as ephedrine or amphetamine.

Treatment of Eclampsia

Q.—*What is the modern treatment of eclampsia, occurring before the onset of, and during, labour?*

A.—The modern treatment of eclampsia is based largely on the views of Stroganoff. It is believed that the danger of the condition depends on the number of fits, and that external stimuli are important in the causation of fits. The treatment, therefore, consists in placing the patient in a quiet, darkened room, reducing external stimuli to the minimum, and giving sedatives to lower the sensitivity of the central nervous system. Paraldehyde is preferred as a sedative in many clinics and is given per rectum in a dose of 6 drachms, repeated in 4 hours and again in 6 hours. If the patient is restless, morphine with atropine may be given in addition, but large doses of morphine should be avoided. Expectant treatment is advised in most cases of eclampsia occurring before labour, though pregnancy should be terminated within a day or two after the fits are controlled.

When eclampsia occurs during the course of labour the membrane should be ruptured when the cervix is half dilated. When the cervix is fully dilated forceps delivery should be employed. Any obstetric abnormality should receive the appropriate treatment. Caesarean section may occasionally be the treatment of choice, especially after the fits have been controlled in a case where the child is alive and viable. Caesarean section may also be needed in cases of severe eclampsia where medical treatment fails to control the fits.

The above is only an outline of the principle of the modern treatment of eclampsia. For a more detailed answer, and for special methods of treatment, the questioner is referred to *Antenatal and Postnatal Care*, by Prof. F. J. Browne (5th edition, Churchill, London, 1944, pp. 377 *et seq.*).

Pruritus and Glycosuria

Q.—*A woman of 33 has suffered from severe pruritus vulvae for over five years. In January and April, 1945, urine examination gave +++ result for sugar. Within the last six months she has lost about 10 lb., feels nervous and shaky, easily exhausted, and has great craving for sweets and bread. Urine now free; blood-sugar-tolerance curve: fasting 83 mg., half an hour after glucose 160 mg., 1½ hours after glucose 100 mg., two hours after glucose 87 mg. (capillary blood findings). Is it likely that an undue amount of sugar is present in the tissues of the vulva and gives rise to irritation? If so, should insulin be used in small doses to assist the synthesis of glycogen in liver and muscle and to reduce the amount of sugar in the tissues? The restriction of carbohydrates in the diet is difficult because of her craving for them and the loss of weight.*

A.—This question is difficult to answer satisfactorily and some further information is needed about the diet. The sugar tolerance is normal and consequently excludes the diagnosis of diabetes mellitus. It is possible that the present diet is very low in carbohydrate and that the patient has a mild diabetes which has recovered with dietetic treatment. If so the pruritus should have disappeared, and it does not seem likely that it is in any way connected with glycosuria. There is no evidence to suggest that there is any difference between the sugar content of the vulval tissues and that of the blood. If the diet contains less than 150 grammes of carbohydrate it should be increased to 200 or 250 grammes, as the patient is losing weight. If glycosuria returns and a high blood sugar is confirmed, insulin should be given in adequate amounts. It is suggested that another cause for the pruritus should be sought.

Tenderness of Muscles

Q.—*For more than three years a patient has suffered from tenderness of the voluntary muscles. At times the slightest pressure on a muscle gives intense pain. Sometimes there is aching, but usually there is pain only on pressure. A slight pinch produces agony. His general health is good. What might be the cause?*

A.—It is difficult to refer these symptoms to any recognizable lesion of the neuromuscular system. It is assumed that care has been taken to exclude peripheral neuritis and also occupational disease; puzzling symptoms are sometimes produced by chemicals used in industry. It is equally difficult to attribute the symptoms to neurasthenia, for, although they might be affiliated with the "rheumatism" and "fibrositis" of neurasthenia, the other symptoms of that disorder are apparently absent. The systematized pattern of the complaint suggests an underlying physical or biochemical abnormality. Biopsy of muscles is easily performed and might provide information of value in this patient. An *x*-ray examination of the muscles for parasites, calcification of ligaments, etc., might also be helpful. The blood chemistry should be investigated, particularly the blood sugar, serum calcium, and erythrocyte sedimentation rate. If none of these investigations gives a clue to the cause, symptomatic treatment with the vitamin B complex should be tried, including large doses of B_1. Wide-field irradiation with ultra-violet or infra-red rays might also give relief.

LETTERS, NOTES, ETC.

Venereology

Brigadier T. E. **Osmond**, Honorary Consultant in Venereology to the Army, writes: As I was mainly responsible for the introduction of the word "venereologist" into "Army medical jargon" I feel it incumbent on me to answer the letter of Lieut.-Col. Henry Richards (Sept. 22, p. 414). It must be admitted that the word is a hybrid, but "English contains thousands of hybrid words, of which the vast majority are unobjectionable" (Fowler: *Modern English Usage*, p. 241). In any case "venereologist" is preferable to "dermatologist," which it supplanted. But the difficulty lies deeper; the term "venereal disease" officially refers to syphilis, gonorrhoea, and soft chancre, yet many patients suffering from these diseases may be exculpated from "venery." For many years doctors have been searching for a more suitable word than "venereal" but without success. Parenthetically an "-ologist" is a person who makes a study of a subject but is not necessarily an "expert practitioner" in it. Criticism, to be of value, should be constructive: Col. Richards's seems to be destructive. Having forgotten much of the classics which I learned at school I consulted a friend who is an eminent classical scholar. He admitted that he found the problem difficult, but tentatively suggested "aedoeologist," from the Greek *αἰδοῖα*, or "aphrodisiologist" from *ἀφροδίσιος*; either word can mean pudenda. Admittedly neither word contains any reference to disease, but nor do ophthalmologist or laryngologist. It is to be feared that neither of the words suggested will prove acceptable, but can Col. Richards or any of your readers suggest a better?

Digestive Disorders and Swallowed Sputum

Dr. P. A. **Galpin** (Plaistow) writes: With reference to the question and answer on digestive disorders and swallowed sputum (Sept. 8, p. 341), from the reply given is one to assume that there is no risk to patients suffering from chronic sinusitis or bronchiectasis in swallowing muco-pus, and that one can trust the gastric secretions to deal with any infection? From my own experience I have noted many children suffering from post-nasal catarrh, who have not learned to spit, frequently have nausea or abdominal pain. In my opinion this has been due to swallowing muco-pus, and I have therefore endeavoured to persuade the parents to train the children to avoid swallowing muco-pus—in other words, to learn to spit. Two or three questions come to one's mind. Which is the factor in gastric secretion which has bactericidal properties? Is it hydrochloric acid? If this is so then patients with hypochlorhydria are at a definite disadvantage, and it would seem to me that patients debilitated after acute catarrhal conditions following measles or whooping-cough may be producing gastric juice deficient in bactericidal power. The surgeon has great faith in the bactericidal power of the peritoneum, but he does not willingly allow abscesses, whether acute or chronic, to spill over in the peritoneum.

Neutralizing Gastric HCl

Mr. E. H. **Johnson** and Mr. J. **Duncan** write: The treatment of peptic ulcer as described in your "Any Questions?" page of your issue of Sept. 1 mentions the importance of maintaining a stomach acidity in the region of *p*H 3.5 in order to promote healing of the ulcer by the inactivation of the pepsin. The maintenance of this continued neutrality can be accomplished by adequate dosage of aluminium hydroxide. Aluminium hydroxide alone of the common antacids possesses the property of neutralizing the gastric hydrochloric acid to a maximum *p*H of 3.5 to 4.0; excess dosage after the initial neutralization serves to maintain this favourable condition by the neutralization of further secretion. This important property of aluminium hydroxide was indicated in a recent paper upon the "Chemical Testing of Antacids" given by us at the British Pharmaceutical Conference held on July 18, 1945.

Early Treatment of Bell's Palsy

Dr. J. L. **Thomas** (Brynmawr) writes: The article by Mr. H. P. and Dr. Cecily Pickerill on the above subject (Oct. 6, p. 457) recalls with interest that, about fifty years ago, while in colliery practice in Glamorganshire, I had a case of Bell's palsy (catarrhal) in a young miner who was a promising public singer. While assiduously, but ineffectively, treating the case electrically, by good fortune I read of Robert Jones—always a friend of weak muscles—using in such a case mechanical means to draw the sound side of the face towards the paralysed one. I resolved to imitate his treatment by using strips of plaster, and after one month the result was highly successful—and very cheering.

Corrigendum

By a slip of the pen the title of Wing. Cmdr. Kenneth Bergin's letter (Oct. 13, p. 508) was made to refer to the Army; the heading should have read: "Psychiatry in the R.A.F."

BRITISH MEDICAL JOURNAL

LONDON SATURDAY OCTOBER 27 1945

THE INCIDENCE AND CAUSES OF BLINDNESS IN THE BRITISH COMMONWEALTH

BY

ARNOLD SORSBY, M.D., F.R.C.S.

Research Professor in Ophthalmology, Royal College of Surgeons of England and Royal Eye Hospital

Only a tentative estimate of the number of blind and the barest of assessments of the causes of blindness in the British Commonwealth as a whole are possible. Fairly complete data are available for England, Wales, and Scotland, but those for other parts of the Empire vary between being relatively adequate to negligible. Any final analysis is therefore out of the question.

1. THE NUMBER OF BLIND

The two fundamental difficulties in assessing the number of blind are the lack of a universally accepted definition of blindness and the lack of uniformity in the methods employed for collecting blind statistics.

In the census returns of most countries information is sought on physical and mental infirmities in the population. Those totally blind are asked to declare this fact. The census returns therefore deal with total blindness as determined by a lay assessment. A lay assessment also enters largely into the statistics supplied by voluntary agencies caring for the blind, though total blindness is not generally the only criterion used by such agencies in granting benefits. Statistics from such sources are far from comprehensive, as they deal with only that section of the blind population which seeks charitable relief, and their extent is, moreover, determined by the energy and resources of the agency in question; furthermore, lay assessment is still the general rule and appears to be particularly capricious when total blindness is no longer the criterion.

In contrast to these two distinctly fallible methods is the one that has emerged only recently as a result of the administration of the Blind Persons Act of 1920. Under this Act statutory benefits were made available to the blind in England, Wales, and Scotland, admission to the Register being obtained on medical certification—which of late has generally meant certification by an ophthalmologist. The data thus obtained have therefore considerable uniformity, but still cover only those who seek the statutory benefits that the Act allows. The fundamental difficulty as to what constitutes blindness is masked rather than solved by the statutory definition of "so blind as to be unable to perform any work for which eyesight is essential." In practice this has been interpreted—somewhat arbitrarily—to mean vision of 3/60 or less with a full field, or better central vision when associated with specified field defects.

For England, Wales, and Scotland data on medical certification by a definite, even if controversial, standard are thus available, and these data are limited only by the fact that not all blind persons seek certification. Elsewhere census returns are still the main source of information, but for some years now there has been considerable criticism of such returns. The data thus obtained have come to be regarded as so unreliable as not to be worth the trouble of collecting, and inquiries for personal infirmities have been discontinued in the censuses for 1921 and 1931 in Great Britain and in that for 1940 in the U.S.A. None the less census data are the fullest that are available for the greater part of the Commonwealth, and critically interpreted they are of considerable value, as will be shown in what follows.

British Isles

England and Wales.—In 1911, when the last census which sought information on infirmities was taken, there were 26,336 persons who declared themselves totally blind. When the Register under the Blind Persons Act was established there were found to be 25,840 eligible—a close approximation to the census figures. The number of registered blind has, however, increased steadily year by year, as the following figures show:

Year	Number on Blind Register	Year	Number on Blind Register
1920	30,785	1933	63,408
1921	34,894	1936	67,534
1923	36,518	1938	71,875
1925	42,140	1940	74,418
1927	46,822	1942	75,306
1929	52,727	1943	76,507
1931	60,598	1944	76,145

There is, of course, no reason for believing that the incidence of blindness has increased during 1920–44 in the startling proportions suggested by these figures; these merely represent an increasing efficiency in the registration of the blind. They furthermore indicate that registration has become fairly effective during recent years. It is also clear that the census figures were a gross underestimate, but it must be borne in mind that the criteria of blindness adopted for these two different returns were different; for the census it was total blindness, for the purpose of the Blind Persons Act it was—in practice—3/60. That the census returns were not quite meaningless is shown by the following findings: An analysis of 9,522 blind certificates in the Counties of London and Middlesex (Sorsby, 1945a) showed that 1,013 were totally blind and 1,822 had perception of light only. The rest mostly had vision up to 3/60. Thus some 2,835 qualified for what a layman would regard as total blindness, making 29.9% of all registered blind in these areas. If it is taken that 30% of all the registered blind in the country are blind in the lay sense indicated (i.e., no perception of light and perception of light only), an incidence of blindness approximating that shown by the census figures of 1911 is obtained. It is impossible to assess the number of blind persons who have not sought registration. At hospitals one still sees certifiably blind patients who have not been registered, while an unknown proportion for various reasons decline certification. It is safe to conclude that the number of blind people in England and Wales is not less than 80,000 and is unlikely to exceed 100,000.

Scotland.—The census for 1911 showed 3,317 blind persons in a population of 4,760,904 (or 70 per 100,000). The number of registered blind persons was 4,104 in 1919—a close approximation, as in England and Wales, to the census figure. But again as in England and Wales it has risen steadily, the rise being confined to the years up to 1929.

Year	Number on Blind Register	Year	Number on Blind Register
1919	4,104	1933	8,678
1921	5,138	1936	8,500
1923	5,754	1938	8,973
1925	6,332	1940	8,908
1927	6,939	1942	8,891
1929	8,518	1944	8,804
1931	8,821		

The Dominions

Canada.—The census figures for 1931 showed 7,343 blind persons in a total population of 10,376,786 (or 71 per 100,000). Statutory benefits for the blind were introduced by Act of Parliament in 1937, and by July, 1938, there were over 3,000 applicants for blind pensions. This was distinctly less than the 4,712 blind on the registers of the Canadian National Institute for the Blind in 1927, but the number of registered blind (? under the Act of 1937) had risen to 12,854 by 1944. It would therefore seem that in Canada the experience of England and Wales is being repeated, and that the number of registered blind is likely to increase. In Newfoundland the number of registered blind in 1944 was 219. The 1911 census showed 287 blind in a population of 242,619 (118 per 100,000).

South Africa.—In an official inquiry carried out in 1936 concurrently with the census there were 1,624 blind amongst the white population of 2,003,857, or 81 per 100,000. No adequate data are available for the coloured population: the same inquiry covering 769,661 coloured persons, excluding Bantu and Asiatics, showed 981 blind (127.7 per 100,000). At the end of December, 1940, the South African National Council for the Blind had detailed information regarding 17,263 blind persons in the Union; there were 1,828 Europeans, 1,632 coloured, and 13,803 natives. Since then, and especially since 1942, when the payment of an increased grant to blind natives was introduced, the Council has been "inundated with registrations of blind natives and the total had increased by leaps and bounds." Recently the Act allowing grants to blind people has been amended to include Indians. There is as yet no information as to the number of blind Indians in the country. By December, 1943, the total number of registered blind had risen to 30,834, and consisted of 2,103 Europeans, 1,887 coloured, and 26,844 natives. On the basis of an estimate of the population supplied by the Director of Censuses the rate per 100,000 at the end of 1942 for the three different communities was: European 91, coloured 211, natives 351.

Australia.—The 1933 census for the Australian Commonwealth showed 3,898 blind in a population of 6,229,839 (63 per 100,000).

New Zealand.—The census for 1916 showed 570 blind in a population of 1,009,449. The New Zealand Institute for the Blind in 1936 estimated the number of blind at 1,000 for the whole country, or 70 per 100,000 (against 56 shown by the census of 1916). It had records of 720 blind, and of these 688 were totally blind. (It is unlikely that with 688 known cases of "total blindness" the total number of blind, by English standards, would be only 1,000.)

The total white population of Canada, Newfoundland, South Africa, and Australasia is of the order of 20 millions. The census rates of blindness per 100,000 were 71 for Canada (1931), 118 for Newfoundland (1911), 81 for South Africa (white population, 1936), 63 for the Australian Commonwealth (1933), and 56 for New Zealand (1916). These are not dissimilar from the census rate of 73 for England and Wales and 70 for Scotland in 1911. If it is concluded, on the strength of experience in England and Wales since the working of the Blind Persons Act, that the actual rate is about 200–250 per 100,000 (on the basis of a computed number of 80–100,000 blind in a total population of 40,000,000), the total of blind amongst the white population of the Dominions is of the order of 40–50,000.

Other Possessions

India.—The census for 1931 showed 606,360 blind in a population of 352,837,778—a rate of 172 per 100,000. It is generally agreed that this is a considerable underestimate. If the rate of blindness known for England and Wales applied to India, its population of over 400,000,000 would provide 800,000 to 1,000,000 blind. But blindness in India is far more common than in England and Wales, and it appears that Indian census figures on blindness are grossly vitiated by the widespread illiteracy and by superstitious fears. On studies undertaken in selected areas both Henderson and Kirwan hold that the census figures indicate only one-third of the blind in India; Megaw puts it as low as one-quarter. Moreover, even these observers, in speaking of blindness, use a considerably lower criterion than that now used in England—i.e., counting fingers at one metre instead of 3/60. At the very least the census figure of 606,360 must therefore be multiplied by three or four. This gives the number of those totally or subtotally blind as between 2 and 2½ millions. For the present this must be accepted as a minimum figure. The actual number is likely to be considerably more, for India is one of the classical countries of blindness, and according to O'Dwyer "there is no country in the world to-day where the affliction of blindness is so widespread." This being so, a comparison with Egyptian and Palestinian figures rather than with those for England and Wales is called for. In both Egypt and Palestine the census figures indicate a rate of blindness 10 to 15 times that for England and Wales. On that basis the blind in India number between 10 and 15 millions.

Ceylon.—The census for 1921 showed 4,005 blind in a population of 4,498,605—a rate of 89 per 100,000. There is no reason for believing that the situation in Ceylon is substantially different from that of India, and the census figure must be regarded as a serious underestimate.

Egypt.—The appalling rate of 1,325 blind per 100,000 was recorded by the census of 1907. Ten years later it had declined to 1,222, whilst in 1927 it fell to 775 (109,934 blind in a population of 14,177,864).

Palestine.—Palestine has the world's highest census rate for blindness. It was 843 per 100,000 in the 1931 census (8,172 blind in a population of 969,268), surpassing the rate of 775 recorded for Egypt in 1927. In contrast to the high rate for the Muslims of the country, that for the Jews is relatively low, and for Christian Arabs intermediate between the two (Muslims 1,061, Christians 564, Jews 139 per 100,000).

African Colonies.—No adequate data are available for the greater part of Africa. The native population in Uganda in 1911 showed a census rate of blindness of nearly five times that of England and Wales (354 against 73 per 100,000). It is not known whether blindness in the native population in Africa is of the order of frequency seen in India, Egypt, and Palestine. That blindness is extremely frequent, and indeed far more frequent than anywhere else in the world, is suggested by the following findings concerning natives in the Union of South Africa: Rosset-Berdez (1944) in an inquiry for the South African Government examined 4,500 natives; only 527 (13.2%) were normal; 214 (5.3%) were totally blind; 360 (9.0%) had lost one eye as a result of disease.

Pacific Islands.—Information is scanty. The census for 1911 for the Fiji Islands showed 1,385 blind in a population of 137,248, giving a rate of 1,009 per 100,000—i.e., a rate of the order of Egypt and Palestine. It is not known whether the Fiji Islands can be regarded as typical of Indonesia.

It is obvious that, whatever be the definition of blindness, no final assessment of the number of blind in the British Commonwealth is possible. A fairly clear indication is available for the 46,000,000 in England, Wales, Scotland, and Northern Ireland: it cannot be less than 90,000 and is likely to exceed 100,000. For the 20,000,000 whites in Canada, Newfoundland, Australasia, and South Africa the number of blind is likely to be 40–50,000. As for the native populations of the British possessions in Africa, Asia, and Indonesia, their blind would number about 1¼ million if blindness were no more common among them than it is in the British Isles and the Dominions, but it is likely that the actual figure is considerably more than 10 millions.

2. THE CAUSES OF BLINDNESS

Data on the causes of blindness in England and Wales and in Scotland are fairly adequate. Elsewhere the information is scanty.

England and Wales.—No less than 77.2% of the 76,507 registered blind in 1943 were over 50 years of age; 20.8% fell in the age group 16–50 years, and 2.0% in that of 0–16 years. Analyses of the data as to the age at onset of blindness do not affect substantially the outstanding fact that in most cases blindness is an affliction that, in the phrase of the *Iliad*, sits on the sad threshold of old age. As to the causes of blindness, the Prevention of Blindness Committee (1938) gives an analysis of 5,290 blind certificates and the Northern Counties Association for the Blind (1938) of 10,000 certificates. Both agree in placing cataract first with 25.0% and 33.6% of the total respectively; in both series glaucoma takes the second place with 11.8% and 10.0% respectively. Defects of congenital, hereditary, and developmental origin, and myopia take the third and fourth places in the first series (with 11.0% and 10.2% respectively), and occupy the reverse order in the second (with 7.0% and 8.5% respectively). Taken together, these four causes—cataract, glaucoma, defects of congenital, hereditary, and developmental origin, and myopia—account for 58.0% in the analysis of the Prevention of Blindness Committee and 59.1% in that carried out by the Northern Counties Association for the Blind. Substantially the same result was obtained in an analysis of 9,562 registered blind in the Counties of London and Middlesex (Sorsby, 1945a). Cataract and glaucoma again took the first and second places with 21.2% and 14.0% respectively, whilst myopia accounted for 12.1% and defects of congenital, hereditary, and developmental origin for 10.4%, the total for the four main causes being 57.7%. When this series of 9,562 cases is analysed in age groups a considerably different picture emerges.

(1) In the age group 0–14 years (143 cases) defects of congenital, hereditary, and developmental origin lead with 67.1%, and ophthalmia neonatorum is second with 5.6%, the remaining causes all being considerably less significant.

(2) In the age group 15–29 years (656 cases) defects of congenital, hereditary, and developmental origin still lead with 38.4%, with congenital syphilis in the second place with 14.0%.

(3) In the age group 30–49 years (1,303 cases) the leading cause is still as in the other two age groups, this time with 21.3%, and with myopia in the second place with 15.5%. Congenital syphilis is now third with 13.1%.

(4) In the age group 50–69 years (3,541 cases) myopia leads with 18.6%; glaucoma and cataract come second and third with 15.2% and 14.0% respectively.

(5) In the age group of 70 years and over (3,725 cases) cataract is responsible for 39.3% and glaucoma for 19.3%, with senile macular lesions in the third place with 11.7%.

The numerical frequency of cataract and glaucoma, which is so striking a feature in the statistics for the blind population, gives an exaggerated significance to these two causes. When the causes operative in the different age groups are evaluated in terms of years of expectation of life—i.e., in expected years of blindness—cataract falls from the first place to the third with 13.1% of the total of expected years of blindness, and glaucoma falls from the second to the fourth place with 10.0%. Defects of congenital, hereditary, and developmental origin, which in order of frequency are fourth, now assume a preponderant first place with 22.9%, and myopia takes the second place with 16.0%. The congenital and congenitally determined anomalies (such as myopia) together are thus responsible for no less than 38.9% of the total of expected years of blindness, whilst cataract and glaucoma together, though numerically so outstanding, account for considerably less—viz., 23.1%. On this reckoning congenital syphilis is also a cause of some importance, accounting for 8.8%, with ophthalmia neonatorum not far behind (6.2%). If these provisional data on the blind in London and Middlesex apply to England and Wales as a whole, the major causes of blindness are not cataract and glaucoma but, in order of frequency, defects of congenital, hereditary, and developmental origin, myopia, cataract, glaucoma, congenital syphilis, and ophthalmia neonatorum.

Scotland.—As in England and Wales most of the blind are over 50 years of age (the actual percentage for 1943 being 74.1 against 77.2 in England and Wales). Marshall and Seiler's study of 2,885 registered blind in Glasgow and South-West Scotland places myopia as the first of causes with 15.9%; cataract, chronic septicaemia, glaucoma, and congenital anomalies follow with 15.2%, 10.9%, 8.9%, and 8.1% respectively. Ophthalmia neonatorum occupies the eighth place with 3.4%. Calculated in years of blindness the patients in these different categories had experienced, chronic septicaemia comes first (with an average of 12 years); congenital, hereditary, and developmental anomalies second (11.4 years); myopia third (10.3 years); and ophthalmia neonatorum fourth (10.1 years). Cataract and glaucoma come low with the eighth and tenth place respectively. These findings agree with those for London and Middlesex on the significance of defects of congenital, hereditary, and developmental origin, and of myopia as foremost causes of blindness.

The Dominions.—No adequate data are available. There are various analyses of returns from blind schools and institutions and from records of patients seen by ophthalmologists in practice. They give the impression that in Australia, New Zealand, and Canada, at any rate, the same causes of blindness operate as in the British Isles. Registers of blind persons, comparable in completeness as to numbers and causes, do not appear to be available for any of the Dominions, except possibly South Africa. Here a register in the process of formation provides data on the causes of blindness in 26,844 natives and 2,103 whites registered by December, 1943. The main causes recorded were:

	White (2,103 Cases)	Native (26,844 Cases)
	%	%
Cataract (senile, traumatic, and unspecified) ..	9·7	42·6
Syphilis	11·2	5·8
Glaucoma	7·2	2·4
Trachoma	5·0	2·0
Local infections of coats of eye	4·5	8·9
Ophthalmia neonatorum	4·4	0·8
Congenital, hereditary, and developmental defects (including congenital cataract)	20·9	1·2

Without a fuller knowledge of local conditions and the way these data were collected, the interpretation of these findings is difficult. A significant observation is the finding of trachoma in 135 natives out of 10,591 examined in a special investigation (Rosset-Berdez).

India.—Several analyses of the causes of blindness in relatively small series are available. In a series of 2,750 reported by Megaw cataract was responsible for 23%, glaucoma and smallpox for 9.0% each, and trachoma for 8.0%. In a series of 2,044 blind eyes Gnanadikam found that among those blind in both eyes the order of frequency of the causes was glaucoma, corneal ulcer, keratomalacia, trachoma, iritis, smallpox, and gonorrhoeal ophthalmia. Another observer (Bagchi) gives the following order of frequency in 3,404 persons blind in one or both eyes: anterior staphyloma, 39.7%; trauma, 7.0%; trachoma, 6.2%; leucoma, 5.9%; keratomalacia, 5.5%. In 74 inmates of the Calcutta Blind School Indra found the following distribution: congenital, 15 cases; smallpox, 11; syphilis, 10; ophthalmia neonatorum, 5; keratomalacia, 4—the last being regarded as an underestimate of the frequency of the affection, "as few such children can afford the expenses of the Blind School." Wright (1937) gives the principal causes in order of importance as:

In Children	*In Adults*
Keratomalacia	Cataract
Ophthalmia neonatorum	Optic atrophy (mainly syphilitic)
Congenital syphilis	Corneal ulcers
Hereditary blinding disease	Glaucoma
	Trachoma

while in both children and adults irritant remedies (the result of ignorance and the lack of adequate facilities for treatment) and smallpox are potent factors. All these assessments have one thing in common: the immense amount of blindness caused by various uncontrolled infective processes and by malnutrition.

Egypt.—In a cumulative list of causes of blindness published in the reports of the ophthalmic hospitals the predominant cause of blindness in some 75,000 cases [? eyes] are shown as conjunctivitis with corneal complications and its sequelae. Some 82% of all blind fell into this category, and it appears that acute ophthalmia rather than trachoma is the main form of conjunctivitis leading to blindness. Glaucoma is also a cause of some significance.

Palestine.—The reports of the Ophthalmic Hospital of the Order of St. John, Jerusalem, give a parallel analysis to that in the Egyptian reports and the findings are similar. Some 78% of all blindness is caused by conjunctivitis and its corneal complications. Shihab (1937) holds that some 75% of all blindness is caused by the acute ophthalmias, and that the two extremes of age are most susceptible.

Trinidad and Tobago.—In a study of the causes of blindness in 194 patients Métivier found syphilis the cause in 45 instances, glaucoma in 38, and leprosy in 14. Other significant factors were cataract and purulent ophthalmia.

African Colonies.—Little is known of the causes of blindness in the African colonies. Trachoma is probably rare but not unknown, as was previously believed. Two recent studies have drawn attention to onchocerciasis (Ridley, 1945; Scott, 1945). It is not known whether the incidence and causes of blindness seen in the natives of the Union of South Africa are typical of the African population as a whole.

3. PREVENTION OF BLINDNESS

In England smallpox figured as the main cause of blindness in such assessments as are available for the early years of the last century. Towards the end of the century ophthalmia neonatorum was the largest single cause; in a collective survey carried out by the Ophthalmological Society in 1884 it was found responsible for between 30 and 40% of blindness seen at blind schools and institutions. These findings may be taken as indicative of the role of infectious diseases as causes of blindness in this country during the last century. To-day infectious disease—both exogenous and endogenous—accounts for only a small proportion of all blindness; in the survey for the Counties of London and Middlesex it stood at not much more than 15% (Sorsby, 1945a). Generally speaking, the most significant cause in the undoubted decline in the incidence of blindness in England, and in advanced countries generally, has been the control of infectious disease by public health measures, adequate facilities for treatment, and of late years the advances in chemotherapy, beginning with arsphenamides in the treatment of syphilis. Other causes in the decline of blindness have been the development of ophthalmology, the rise of eye hospitals and eye departments, and the perfection of operative techniques for cataract and glaucoma.

England and Wales.—The decline in the incidence of blindness in England and Wales is hardly reflected by the mounting number of registered blind since 1920. That a decline has taken place is suggested by the census findings since 1851, which have shown a steady diminution in the rate of incidence per 100,000 with each census. The rate in 1851 was 102; it declined to 96, 95, 88, 81, 78 at the subsequent decennial censuses, falling to 73 in 1911. More definite evidence is supplied by the returns for the age group 5–16 years under the Blind Persons Act of 1920. Unlike those for the other age groups, the returns for this group may be taken as giving a true presentation, for children come under the care of the school authorities, and the blind child is unlikely to escape registration. In contrast to the increase in the total number of registered blind, there has been a striking decline in the number of registered blind children, as the following table shows (Sorsby, 1945b).

Table I.—*Incidence of Blindness in Children aged 5–16 Years, England and Wales, 1823–43*

Year	Population aged 5–16 Years	No. of Registered Blind aged 5–16 Years	Rate per 100,000
1923	7,477,143	2,723	36·4
1925	7,306,761	2,720	37·2
1927	7,385,359	2,554	34·6
1929	7,262,590	2,438	33·6
1931	7,166,056	2,355	32·9
1933	7,246,446	2,089	28·8
1936	6,890,730	1,853	26·9
1938	6,694,300	1,676	25·0
1939	*	1,619	24·2†
1940	*	1,499	22·4†
1941	*	1,425	21·3†
1942	*	1,369	20·5†
1943	*	1,355	20·3†

* Population figures not available for publication. † On 1938 population figures

A decline to almost a half in the space of twenty-one years is a gratifying testimony to the efficacy of the many measures that are operative in the prevention of blindness. But it cannot be assumed that this trend is applicable to the whole blind population. In fact it is likely to be almost entirely confined to the lower age groups. It has already been seen that the causes of blindness are notably different in the different age groups and that nearly 80% of the blind are over 50 years of age. There is no reason for believing that blindness from cataract, glaucoma, myopia, and senile macular lesions—the causes operative in that age group—is declining to any marked extent, while the evidence available for the causes of the decline in the incidence of blindness in the young indicates that the reduction in them is wholly due to the elimination of the sequelae of infectious disease. This is brought out by the following comparative table of the causes of blindness seen at provincial blind schools in 927 children in 1922, and 524 in 1944 (Sorsby, 1945b).

Table II.—*Proportionate Incidence of the Main Causes of Blindness at Provincial Blind Schools in 1922 and 1944*

	Board of Education, 1922 (927 Cases)	Present Series, 1944 (524 Cases)
	%	%
Ophthalmia neonatorum	30·4	9·2
Purulent ophthalmia of later years ..	2·5	—
Phlyctenular ophthalmia	3·7	0·2
Interstitial keratitis	4·1	0·9
Iridocyclitis	2·5	0·8
Choroiditis	?	0·8
Syphilitic lesions	?	2·5
Optic atrophy	12·9	5·3
Congenital anomalies:		
Including myopia	37·2	67·6
Excluding myopia	30·8	55·0

This table shows a striking reduction in blindness from ophthalmia neonatorum and suggests a corresponding decline in blindness from congenital syphilis. As a corollary, blindness due to defects of congenital, hereditary, and developmental origin (in which myopia may be included) has assumed a proportionately increased significance. Two conclusions suggest themselves:

(1) The decline in the incidence of blindness in children is likely to come to an end within foreseeable time, in view of the fact that already some 65% of all blindness in children is due to defects of congenital or congenitally determined origin, and such defects are not readily amenable to treatment. It is therefore likely that blindness in children 5–16 years old will decline from its present rate about 20 per 100,000 to about 12–14 per 100,000, but will remain at that level until more is known of congenital and congenitally determined disease.

(2) No substantial decline of the blind population as a whole is to be expected so long as there is no fuller knowledge of cataract, glaucoma, myopia, and the senile degenerations of the fundus oculi. Such decline as may be expected from better facilities for treatment may well be balanced by the shift towards more people in the higher age groups of the population as a whole.

A century of effort in public health legislation, hospital administration, bacteriology, and pharmacology is reflected in the diminution of the incidence of blindness. The further operation of these forces is likely to reduce blindness still more, but at an ever-diminishing rate. Substantial advances can only come with intensive studies of the nature of genetic disease and intra-uterine infections on the one hand, and of cataract, glaucoma, and senile degenerations on the other. These are not all exclusively ophthalmic problems, any more than was blindness from infectious processes. In ophthalmology, however, these problems in pathology have become formulated perhaps more clearly than in other specialties.

Scotland.—In Marshall and Seiler's study of 3,219 blind persons 113 were aged 0–15 years, and of these 37 were blind from defects of congenital, hereditary, and developmental origin, and 3 from myopia. This is a considerably lower incidence than that noted for the provincial blind schools of England. Proportionately there was more blindness from infectious disease. For the higher age groups their findings are essentially parallel with those for London and Middlesex.

The Dominions.—In the absence of more definite data it may be assumed that the problems of the prevention of blindness in the white population are similar to those established for the British Isles.

Africa.—The limited inquiry of Rosset-Berdez for South African natives suggests that one in every twenty Africans is blind. If this is true and applies to Africa as a whole, it is unbelievable that such a state of affairs is not largely remediable. Fuller information is an urgent first step.

India.—Such Indian blind statistics as are available give prominence to lesions like anterior staphyloma (39.7% in one series), leucoma, and corneal ulcer. Trachoma is known to be endemic in some parts of the country; smallpox is still a significant cause of blindness, while ophthalmia neonatorum and congenital syphilis are recognized as important causes of blindness in children. All this is reminiscent of England at the beginning of the last century. The control of blindness in India is thus largely a problem of the control of infectious disease. That this is not purely an issue of pathology and pharmacology is obvious enough from the history of public health in Western Europe, and is grimly emphasized by the fact that keratomalacia—a nutritional deficiency disturbance—is ranked as first among the causes of blindness in children. The problem of blindness in India is not one of the elimination of a particular infectious disease such as trachoma or the acute ophthalmias. It has to be conceived in terms of standards of living, education, facilities for treatment, and adequate and well-trained ophthalmic personnel. None the less there is much that can be done immediately both outside and as part of the long-term plans—how much, can be seen more clearly from a consideration of the position in

Egypt and Palestine.—Here the social problems are not dissimilar in their broad aspects from those seen in India, but unlike in India two clearly defined infectious diseases are the main causes of blindness—the acute purulent ophthalmias and trachoma. Purulent ophthalmia, the more significant cause, is now easily treated by the sulphonamides and by penicillin. An immediate and striking reduction of blindness in Egypt, Palestine (and, indeed, throughout the whole of the Near and Middle East), and perhaps India, could be brought about by the organization of relatively simple treatment stations and possibly mobile units, with adequate supplies of the new chemotherapeutic and antibiotic agents. Trachoma, too, could be considerably reduced by such stations, for the beneficial effect of sulphonamide therapy in trachoma is no longer open to doubt; moreover, there are indications that penicillin may also be highly effective. The creation of such treatment stations will in any case have to be undertaken in any long-term programme, but a sense of urgency has now been supplied by the availability of the new therapeutic agents, for each day that such treatment is not available to the millions of Africa and Asia adds many blind to the roll of the avoidably blinded.

Summary

1. The number of blind in the British Isles is not less than 90,000 and is likely to exceed 100,000. In the white population of the Dominions it is between 40,000 and 50,000. In the native population of the British possessions in Africa, Asia, and Indonesia it is considerably more than 10 millions.

2. There has been a marked decline in the incidence of blindness in childhood in England and Wales during the past 21 years, but there is no evidence that there has been any substantial decrease in the older age groups. Before long the decline in the incidence of blindness in childhood will come to an end, as already about 65% of all blindness in children is due to congenital and genetic infections not readily amenable to treatment. With the rapid elimination of blindness due to infectious disease, intensive research in the problems of genetic disease, maternally transmitted infections, cataract, glaucoma, and the pathology of senescence, has become an immediate task if the incidence of blindness in England and Wales is to be reduced.

3. In the native populations of the British possessions the incidence of blindness could be reduced immediately and effectively by the organization of facilities for the intensive exploitation of the sulphonamides and penicillin in the treatment of the widely prevalent ocular infections.

OBSERVATIONS ON OEDEMA OCCURRING DURING THE COURSE OF MACROCYTIC ANAEMIA

BY

E. G. HOLMES, M.D., M.R.C.P.
Lieut.-Col., R.A.M.C.

"Tropical" or "nutritional" macrocytic anaemia is described in the textbooks, and Wells in India, Trowell in Africa, and a number of other workers have investigated it. Unfortunately, Service conditions render this literature inaccessible, and in this account of certain features of the disease which seem of practical importance I may be treading on ground that has already been covered. Reference to previous work is omitted from necessity, not from negligence.

The textbooks describe the disease as an anaemia, often severe, of a macrocytic type, occurring in India, Africa, the Balkans, and southern United States, among populations suffering from poor nutrition. It is often seen in pregnant women. It is accompanied by fever, diarrhoea, sore tongue, and sometimes oedema (which seems to have been referred to cardiac decompensation). Achlorhydria is said not to occur. Haemolytic and non-haemolytic types of the condition are distinguished.

Discussion with fellow officers suggests that many cases of this kind occur in South-East Asia Command; most commonly among Indian troops, less so among East Africans, occasionally among West Africans, and hardly ever among British soldiers. It is proposed to discuss a series of 38 cases among East Africans, laying stress on certain features.

Table I shows the frequency with which the signs and symptoms mentioned above were observed in this series. Anaemia of a more or less severe degree was noted in all (several patients had blood counts of less than one million red cells when they came under observation). It is not proposed to comment especially on the cytology, which conformed to the textbook description. Macrocytosis was observed in all cases, and normoblasts were seen on a number of occasions. The absence of an adequate centrifuge precluded determinations of mean corpuscular haemoglobin concentration, or of other features requiring haematocrit readings. On several occasions the cells were reported to be macrocytic and hypochromic. Sternal puncture was done in several cases. It always revealed an actively normoblastic marrow. Sickling of the red cells was never observed, nor was increased fragility, even in cases which were clinically of a haemolytic type. No neurological lesions of any kind were noted.

TABLE I

Total cases	38
Glossitis	12
Gastric HCl after histamine:	
Absent	12
Present	16
Not determined	10
Jaundice	5
Splenomegaly	12
Diarrhoea	17
Oedema and/or ascites	12

While gross anaemia can be missed only through negligent examination, it will be obvious that the other signs and symptoms, except the oedema and ascites (which will be discussed more fully) and the achlorhydria, may be attributed to a number of complaints very common in South-East Asia Command. Haemoglobin determinations alone are insufficient to exclude a moderate anaemia of this type. The only safe procedure is to count the red cells as well as to estimate the haemoglobin. At the least, a well-prepared thin film should be examined by a reliable observer. In this hospital some cases were certainly missed before this point was appreciated.

Fever is usual in the more severe cases, and may be mistaken for that of malaria or other illnesses. Diarrhoea may be attributed to dysentery or to infestation with worms or flagellates. Several cases at first labelled "non-specific diarrhoea" proved later to be macrocytic anaemia. Splenomegaly may be attributed to malaria or schistosomiasis; and indeed, in the cases under consideration, it was difficult to be sure whether the enlarged spleens observed were in truth connected with the anaemia or with a legacy from earlier disease. Jaundice, when present, is more likely to suggest infective hepatitis than anaemia.

Prominence of one or more of these signs may lead to a wrong diagnosis unless the possibility of macrocytic anaemia is kept in mind as an underlying cause, and appropriate investigations made.

The occurrence of oedema and ascites merits special discussion. Fairley and Low (1939) attribute it to the cardiac insufficiency. It occurred in 12, or nearly one-third, of the present series of cases; in all but one, however, it did not appear until, as a result of treatment, the blood count had risen considerably. At this time other signs which could be attributed to cardiac decompensation were entirely absent.

Dietary deficiency is known to be a cause of macrocytic anaemia, and although an East African soldier's diet is probably better than that to which he is generally accustomed in civil life, it contains only 41 g. of first-class protein. The manufacture of haemoglobin involves the synthesis of protein as well as the manufacture of the iron-containing haem molecule. For every gramme of iron in haemoglobin there are some 800 g. of protein. If an individual with 6 litres of blood in his body is to raise his haemoglobin by 1 g. per 100 c.cm. of blood he must manufacture 60 g. of protein. It is not uncommon in these cases for the haemoglobin to fall as low as 6 g. per 100 c.cm., in which case to restore it to normal nearly half a kilogramme of protein will have to be forthcoming. Further, the protein moiety of haemoglobin is believed to belong to a class of proteins which are known to be particularly rich in diamino-acids, such as arginine and lysine, and, since there is evidence that these substances cannot be synthesized in the body, proteins which contain them must be eaten. Even so, it is possible that a good many molecules of food or body protein have to be broken down before the necessary constituents can be obtained for the manufacture of a molecule of haemoglobin. This may result, during the periods of blood regeneration, in a very heavy drain on the total protein resources, during which the plasma protein may become depleted.

It has been held that the plasma proteins do not form part of the general protein currency of the body. This can hardly be maintained in view of the work of Schoenheimer and his collaborators, who showed that if amino-acids containing "heavy" nitrogen were introduced into the body either by injection or by feeding, the "heavy" nitrogen atoms could soon be identified in the protein of all the body tissues, including the plasma.

Once the osmotic pressure exerted by the plasma protein falls below a certain critical level fluid can no longer be held in the capillaries, and oedema or serous effusions result. If a diminution of plasma proteins does in fact determine the occurrence of oedema and effusion in these cases it should be possible to demonstrate it, and observations were undertaken with this end in view.

After the work had been planned and started, a copy of the *B.M.J.* for Jan. 13, 1945, became available. This contained a paper by Trevor Davies recording a case of oedema during recovery from anaemia. He found that the total serum protein, when the oedema was fully developed, was 4.16%, the albumin 1.8%, and the A/G ratio 0.76/1. At this time the red cells numbered 3,700,000. A month later, as a result of plasma transfusion and protein feeding, the total serum protein was 5.61% and the A/G ratio 1.5/1. The writer quotes another case of plasma transfusion in severe microcytic anaemia (J. McD. Holmes, 1944)—not available here. He also quotes Heath and Taylor (1936) as stating that for a rise in 10% of the haemoglobin level 80 g. of protein must be retained.

The equipment necessary for plasma protein estimations is not provided in the laboratory of a field hospital, and the method used, based on that of Walther (1941), had partly to be improvised. Details are given in the Appendix to this paper. All the determinations were made on sera, since plasma could not be freed from cells without a centrifuge.

In the first instance a number of estimations of total serum protein were carried out. Though in several instances the total serum protein of cases with oedema was much diminished (e.g., the patient had a total serum protein of 4.9%, with gross oedema, on Dec. 24, 1944) the figures did not clearly establish the point at issue, but the figure for total serum protein may not be a sufficient criterion. The osmotic pressure of the serum depends upon the sum of the osmotic pressures of its albumin and globulin components (that exerted by fibrinogen is very small). The albumin is the smaller molecule, and is said to exert about four times the osmotic pressure of the globulin. A serum in which the albumin is decreased and

* This estimation was done at another hospital, and taken from the patient's notes.

the globulin normal or raised may therefore exert a lower osmotic pressure than a serum of equal or less total protein content but containing a higher proportion of albumin. Stitt gives the following figures as "normal": Total protein, 6.3–8.0% ; albumin, 3.8–5.2% ; globulin, 2.0–3.5% ; A/G ratio, 1.45/1 to 2.2/1.

The total colloid-osmotic pressure is said to lie between 20 and 30 mm. of mercury. Oedema is said to occur if the total protein falls below 5.5% or the albumin below 2.5%. It is clear from this that fractionation of the serum protein is required if the influence of the serum protein in determining the oedema is to be assessed.

Table II gives the results of a number of control determinations on sera of cases without anaemia or oedema. In Table III are given the corresponding figures for anaemic patients, some of whom were oedematous, and for one or two other cases with oedema and anaemia due to other causes.

It will be seen from Table III that Nos. 44131 and G/1419, though grossly anaemic and very ill, were free from oedema or ascites and had serum albumin levels well over 3.0%. No. 40866 on April 24, 1945, was grossly oedematous, and his total protein was very low, although his albumin was only just under 3% and his A/G ratio normal. A comparison of these three cases shows that the A/G ratio, taken alone, has no particular significance (see also No. 14404 in Table II, in which the A/G ratio is low because of increased globulin). No. N/22916 had moderate oedema and ascites on April 29. It was much worse on May 9, by May 30 it was improving, and it had disappeared by June 19. Two determinations on DN/22926 are included to illustrate a type of case in which oedema has long been accepted as being due to lowered serum protein ; while G/3112, who had a little ascites, exemplifies yet another condition with a low albumin and a reversed A/G ratio.

The presence of oedema and ascites in these cases of anaemia has certainly given rise to errors in diagnosis. It often occurs at a stage when the anaemia is not impressive, and at which it may be missed altogether if reliance is placed on haemoglobin estimations alone. Two such cases were evacuated to this hospital with the diagnosis of hepatic cirrhosis, and in another vitamin B deficiency was suspected.

Aetiology and Complications

These are discussed together because I feel in a real difficulty of the "chicken and egg" variety. Certain conditions have been observed sometimes to accompany the anaemia, but whether they are also its cause is very difficult to determine. Table IV gives the conditions which were noted in this series.

TABLE IV.—*Conditions Present*

Ankylostomiasis	11*	Malaria	2*
Pulmonary complaints ..	9*	Scrub typhus	1
Amoebic dysentery	3	Schistosomiasis	1
Bacillary dysentery	1	None	12

* One patient suffered from malaria, ankylostomiasis, and a mild attack of pneumonia.

It will be seen that 12 of the cases suffered apparently from uncomplicated anaemia. Ankylostome ova were found in the stools of 11. In spite of the prevalence of dysentery, in only 4 of these cases was its presence established either during or before the onset of the anaemia. We can find no evidence suggesting that the anaemia was caused by dysentery; the diarrhoea from which many of them suffered was a feature of the anaemia itself, and was not caused by a bowel infection. In only two cases was the presence of malaria parasites established. (This raises a difficulty, because the majority of East African troops come from districts in which malaria is hyperendemic, and one would expect a higher parasite rate. On the other hand, they were all on suppressive mepacrine.) The proportion of respiratory complaints, varying from a mild bronchitis to frank pneumonia, was high. One patient was admitted with pneumonia and developed a macrocytic anaemia while in hospital.

Case DT/1574.—On admission (21/12/44): Temperature 103°, pulse 120, respirations 32. Crepitations at both apices; no frank consolidation. Not clinically anaemic. Given sulphapyridine.

26/12/44: T. normal; chest clear. Sulphapyridine stopped.

27/12/44: Moderate fever; looks pale. Hb 54%, R.B.C. 2,750,000, C.I. 0.99. Slight anisocytosis. W.B.C. 10,975 (P. 67%, E. 12%, L. 16%, M. 5%).

30/12/44. T. 100°. Weak and listless. Weil-Felix and Widal, negative.

5/1/45: R.B.C. 1,830,000, Hb 38%, C.I. 1.05. Anisocytosis, poikilocytosis, polychromasia; myeloblasts and normoblasts present; no sickling.

8/1/45: Put on high protein diet and vegemite.

21/1/45: Reticulocytes 5%.

23/1/45: Hb 82%, R.B.C. 4,630,000. Slight anisocytosis and poikilocytosis. W.B.C. 3,400.

26/1/45: Fractional test meal shows free HCl.

6/2/45: Hb 96%, R.B.C. 5,020,000, W.B.C. 4,100.

It is a pity that a red cell count was not done on admission. However, the blood counts of Dec. 27, 1944, and Jan. 5, 1945, illustrate the development of the anaemia. Large hypochromic red cells were present. The response of this case was particularly rapid. The impression gained from this and other cases is that though respiratory complaints do not cause the anaemia they may precipitate and exacerbate it.

That ankylostomiasis is potent in preventing recovery from anaemia was suggested by two cases in which ankylostomes were found and treatment was given soon after admission. After a time the anaemia failed to improve and further stool examination again revealed eggs. A second "worming" was followed by improvement in the blood count, and no more ova were seen. In face, however, of the number of cases in which neither ankylostomiasis nor any other disease was found, it is difficult to make a case for a causal relationship between the anaemia and any of the infections commonly seen in this theatre.

Of the total cases 31 were evacuated from forward areas, and 7 were admitted from L. of C. units. It is likely enough that the hardships of a particularly strenuous campaign would precipitate the condition in men already predisposed. But these figures may be misleading. At the time when almost all the sick and wounded from the East African Forces came through this hospital, all but a handful of troops were in forward areas. Later, when the division was out of the line, the bulk of the sick were diverted to another evacuation route, and were not seen here.

No apology is made for labouring the above points. In this, as in other instances, prevention is more important than cure. There is danger lest loose statement to the effect that anaemia is "always" due to malaria or ankylostomiasis may blind us to more important underlying conditions such as inadequate diet. In any case it is thoroughly established that the anaemia ordinarily caused by malaria and ankylostomiasis is characteristically of the microcytic type, and therefore different from that here described. To expect a man who has had a diet poor in first-class protein since he was weaned to maintain or replenish his haemoglobin in the face of hard campaigning conditions, with or without added infection, may be to expect him to make bricks without straw.

Treatment

Of this series one patient died from an intercurrent attack of cholera. Three were evacuated (when improving) because of pressure on hospital bed-space, and one was graded Category C on account of an old chronic synovitis of the knee. All the remainder have been returned to duty in Category A except five who are still under treatment. Some of those discharged still had achlorhydria, though three, originally achlorhydric, were found to secrete HCl when reviewed after return from the convalescent depot. Those with persistent achlorhydria all had normal blood counts, had put on weight, made no complaints of dyspepsia, and seemed so well that, rightly or wrongly, the finding was ignored and they were returned to duty. It seems, therefore, that the treatment given may be regarded as satisfactory in a long-term sense. But it has proved very slow: the average duration of treatment (including time at the convalescent depot) was 105 days; the longest 175 days, the shortest 58.

It is stated (Fairley and Low, 1939) that the condition responds to marmite, to liver, to liver extract by mouth equivalent to 1 lb. of liver a day, and to parenteral administration of liver extract. In the haemolytic type the doses of these substances may have to be very large. These authors say that before the introduction of liver therapy the mortality rate was around 40%. Moore, Vilter, Minnich, and Spies (1944), working on a series of cases in America, found that these responded to parenteral liver and to beef muscle by mouth, and further showed that the following substances were without effect: niacin, thiamine, riboflavin, calcium pantothenate, pyridoxine, inositol, para-aminobenzoic acid, and choline.

In the present series the supply of therapeutic substances was too irregular to allow of more than a "shot-gun" regime of treatment. The diet contained about 4,000 calories. There were approximately 165 g. of protein, of which 38 g. were contained in meat (muscle), 22 g. in liver (when available), 31 g. in milk (including cheese), and 12 g. in eggs, giving 103 g. of first-class protein. (Anyone familiar with the supply position of the forward hospitals will realize that not infrequently one or more of these items were not available.) In addition, each patient received 2 to 4 oz. of vegemite (marmite substitute) and 9 multivite tablets per day. Each received an iron preparation twice daily, and for a time 2 oz. of dried yeast. For a considerable period no liver extract for injection was available, and that eventually supplied was of Indian manufacture and doubtful potency. A quantity of liver extract for oral administration was available for some time.

In all, eight patients received liver by injection. In two only was a reticulocyte response observed. Two patients showed a reticulocyte response on vegemite. Eight patients had one or more blood transfusions because of their precarious condition. Three of these were previously given at other hospitals. More would have been given at this hospital but for the difficulty of persuading East Africans to act as blood donors. However, several patients whose condition seemed very precarious, but from whom blood had to be withheld for the reason mentioned, made a good though slow recovery without it.

Treatment of Oedema and Ascites

Five of the oedematous patients received intravenous infusions of reconstituted serum. This treatment was followed by a diuresis, and in three cases the oedema and ascites began to clear up a few days later. In the other two it appeared to have little effect. It is felt that this line of treatment should perhaps have been followed more vigorously. The difficulty was, first, that the amount of serum available was limited, and a good supply had to be conserved for surgical emergencies; secondly, that the giving of serum was usually followed by a sharp rise of temperature and a good deal of malaise and discomfort. The water used to dissolve it had been bottled for some time, and one would have felt happier in preparing fresh pyrogen-free water; no glass still was, however, available. A pint of serum will contain about 40 g. of protein, of which about 22 g. will be albumin; this would raise the serum albumin by about 0.5%.

In the presence of a large effusion the question of paracentesis arises. The fluid contains protein which is for the time being out of circulation, though if the effusion is naturally absorbed it will, presumably become "current coin" again. If, however, part of it is removed by paracentesis, and is replaced again (as so often happens) by further effusion, protein will be irrevocably lost to the body. As an example, on May 28, 1945, 2,570 c.cm.—a very small part of a huge ascites—was removed from the abdomen of No. 40866. This contained 93 g. of protein, of which 40 g. was albumin. The removal of this fluid made little difference to his comfort, and in a few days he was as distended as before. Subsequently (June 19) the oedema and ascites began to diminish, and had all disappeared in a few days. Earlier, N/22916 had had 3,640 c.cm. withdrawn at the cost of 32 g. of protein (which in this case was all globulin). He "filled up" again very quickly. Subsequently the whole effusion was absorbed. It is thought that, unless really serious embarrassment is being caused, effusions in these cases are better left alone.

Conclusion

In writing this imperfect account I have made use of some data,—e.g., the first figure in Table III—contained in the documents of patients transferred from other hospitals, and, in certain cases, of the notes of other M.O.s (particularly those of Capt. R. A. Shanks, R.A.M.C., of this hospital). I am greatly indebted to Major A. B. Raper and his staff, especially S/Sgt. M. Fitch, R.A.M.C., for all the haematological examinations, for routine pathological examinations, and for facilities for carrying out the serum protein determinations.

Summary

A brief account is given of 38 cases of tropical (or nutritional) macrocytic anaemia among East African troops. The aetiology of the condition in S.E.A.C. is discussed.

Particular attention is paid to the occurrence of oedema and effusions. They were observed in nearly 30% of cases, and appear to coincide with the regeneration of red cells rather than with the acute stage of the disease.

A number of estimations of serum protein have been performed. Their significance is discussed.

APPENDIX

The method used for serum protein determination was based on that of Walther (1941) for total serum of plasma protein. 0.02 c.cm. of serum of plasma (measured by means of a haemoglobinometer pipette) is digested with 0.25 c.cm. of sulphuric acid and 0.5 c.cm. of saturated potassium persulphate. The digested mixture is made up to 40 c.cm., nesslerized directly, and compared in a colorimeter against standard ammonium sulphate solution. In the original method a standard correction is applied for non-protein nitrogen, since it is estimated along with the protein nitrogen. In this work boiling-tubes, a spirit lamp, sulphuric acid, persulphate, and Nessler's solution were available, and the laboratory still fortunately yielded ammonia-free water. There was, however, no colorimeter. Fortunately, the commanding officer had brought with him a Lovibond tintometer, and the 0–100 mg. blood-urea disk. These disks are, of course, made for use under the precise conditions laid down by the makers and with Nessler's solution made to a certain formula. These conditions could not be fulfilled, so urea, dried in an improvised desiccator, was weighed out, dissolved, and the solution containing known amounts of urea treated exactly as the serum would be, and used to standardize the disk in terms of mg. of nitrogen per c.cm.

The serum total nitrogen was then determined as described by Walther. After digestion the volume was made up to 25 c.cm. and the nitrogen estimated in the comparator. Dilution, which was achieved by mixing the digest with ammonia-free water in the comparator tube, keeping the final volume 5 c.cm., was carried out if required.

Non-protein nitrogen was estimated by mixing 2 c.cm. of serum, 2 c.cm. of distilled water, and 2 c.cm. of 10% trichloracetic acid, filtering, and digesting 1 c.cm. of the filtrate with 0.1 c.cm. of sulphuric acid and 0.2 c.cm. of persulphate, and making the final volume 10 c.cm. Nesslerization and comparison were carried out as described above. This is not very satisfactory: the colour comparison is often hindered by cloudiness in the tube, due probably to the precipitation of inorganic phosphate. If, on the other hand, this is avoided by greater dilution, the colours (with normal N.P.N. levels) become too pale to be read. With this procedure, of course, the amount of filtrate digested is equivalent to 1/3 c.cm. of serum, instead of 1/50, which is used in the method for total protein. Fortunately, the protein equivalent of the N.P.N. is small, and the inaccuracy involved is not material.

It is worth noting that if the N.P.N. is high the difficulties mentioned disappear, since greater dilution can be used, and the method is then a quick and accurate one (e.g., Table III, No. DN/22926).

The fractionation of albumin and globulin was carried out on the usual principles: 0.2 c.cm. of serum was mixed with 6 c.cm. of 22% sodium sulphate (which was stored in the incubator) and the mixture allowed to stand at 37° C. No filter paper fine enough to filter off the precipitate was available, but by careful pipetting sufficient clear supernatant fluid could be obtained to carry out protein determinations, 1 c.cm. of fluid (equivalent to 1/31 c.cm. of serum) being digested as before. The blank tube contained appropriate amounts of sodium sulphate, sulphuric acid, and potassium persulphate. The result represented albumin nitrogen + N.P.N. The albumin was calculated from this and the globulin obtained from the figure for total protein by difference. All determinations were made in duplicate. Unless the duplicates were in good agreement they were repeated.

It will be appreciated that these methods were used from necessity, not from choice. The employment of so little as 0.02 c.cm. of serum implies an enormous dilution factor and a corresponding exaggeration of random errors. Distillation after digestion is always preferable to direct nesslerization, because of the presence of interfering substances. The lack of a colorimeter was a very severe handicap.

SULPHAEMOGLOBINAEMIA DUE TO ANILINE DERIVATIVES

BY

S. LAZARUS, M.D., M.R.C.P., F.R.F.P.S.

Dispensary Physician, Western Infirmary, Glasgow

The continued use of aniline compounds may produce a marked and persistent cyanosis due to the formation of sulphaemoglobin in the red blood corpuscles. Attention has been directed in recent years to the frequency with which sulphonamide therapy is associated with sulphaemoglobinaemia, but the power of the humbler aniline antipyretics in this direction does not appear to be so well appreciated. Snapper (1925) described two cases of sulphaemoglobinaemia which were due to the continued use of aniline antipyretics. Similar cases have been described by Harrop and Waterfield (1930), Healy (1933), and Morgan and Anderson (1940), among others.

The toxicity of the different members of the aniline antipyretic group varies. The relative toxicity of acetanilide is high, and most of the reported cases of sulphaemoglobinaemia precipitated by aniline antipyretics have been due to that drug. Addiction to it has been observed, and this danger has been emphasized by a number of observers. Acetanilide is now included in Part I of the Poisons List (1937), is not easily available to the public, and hence widespread abuse of it is not to be expected.

Phenacetin presents a quite different problem. It is a component of numerous proprietary headache powders and can be obtained without difficulty. Its chemical structure is similar to that of acetanilide; it is less toxic, however, and cases of chronic poisoning by phenacetin are therefore seldom encountered. In large doses it can, as might be expected, produce poisoning, with effects, including sulphaemoglobinaemia, very much like those seen with acetanilide. Snapper's (1925) two cases of sulphaemoglobinaemia were due to chronic poisoning with phenacetin, and Coxon and Crawford (1940) have reported another. Two cases of sulphaemoglobinaemia have been seen recently, and are described here.

Case I

On April 6, 1943, a housewife aged 42 was admitted to hospital on account of severe headache, weakness, and cyanosis. She had been subject to attacks of severe headache since childhood. These attacks occurred at least once a week and each lasted one to two days. Since the menopause in 1941 the severity and duration of the headaches had increased. The pain began in the crown of the head and then spread to one or other side. The patient could not account for the headaches: she read avidly without ill effect, and was free of nausea and photophobia during the attacks. She shunned company and crowded places, as she feared that an attack might be precipitated in these circumstances. In 1930 she received numerous injections of morphine to ease the headaches. Eighteen months before admission she had noted that her lips were blue, and she stated that her skin had been blue for about a year. This blueness was more pronounced during attacks of headache, and the patient's relatives had remarked on the blue colour of her face. She had taken many brands of analgesic powders for her headaches, but two years before admission she resorted to a proprietary tablet (phensic) which contains approximately 3.6 gr. of acetylsalicylic acid and 2.1 gr. of phenacetin. She took between "4 and 10 tablets daily," according to the severity of the headache. During an attack of pain she had had as many as 30 tablets in a day (=63 gr. of phenacetin).

Her husband stated that in the last attack, which persisted for four days before admission, his wife had taken over 100 tablets. He said that the patient had become very irritable and depressed during the past few months. She was confused when the headaches were severe and kept swallowing tablets without regard to their number. During the past year she had been given 4½ gr. of ferrous sulphate daily and monthly injections of anahaemin, presumably to improve her general condition.

On admission the patient was greatly distressed with headache, but not confused. She was thin and poorly nourished. There was no dyspnoea, but cyanosis was very marked. The skin was a slate-grey colour, which was especially noticeable in the lips, ears, nose, and beds of the nails. The temperature was 99° F., the pulse rate 100, and the respiratory rate 20 a minute. The pulse was regular and of good volume: the arterial wall was not palpable. The area of cardiac dullness was not increased and the heart sounds were well heard. A systolic murmur audible at the mitral area was not conducted. The chest was symmetrical and moved equally on both sides. Further examination did not reveal any abnormality of the lungs. There was no evidence of any mediastinal abnormality. The abdomen was tense, but moved freely with respiration. The liver and spleen were not palpable. Examination of the nervous system did not reveal any abnormality. The optic fundi were normal. The urine was free of albumin, sugar, and blood, but showed the "diacetic acid fallacy" with ferric chloride solution.

Blood examination showed: Hb, 105% (Sahli); red cells, 4,800,000 per c.mm.; white cells, 4,200 per c.mm. The blood films were normal. The venous blood was darker than normal and remained so despite shaking in air. On spectroscopic examination of lysed blood an absorption band was seen in the red portion (612-620 λ) of the spectrum. This band was not affected by the addition of potassium cyanide solution and was presumed to be due to sulphaemoglobin. It was visible in a 1 in 100 dilution of blood in water two days after admission (April 8). No specific treatment was given. The headaches were considered to be psychogenic in type.

Progress.—The acute headache passed off after three days, but the cyanosis remained. Analgesics were withheld, and so far as is known the patient did not have a secret supply. Despite this, it was 16 days before there was any obvious diminution in the cyanosis. Three weeks after admission the cyanosis had lessened considerably, but the sulphaemoglobin absorption band was still present in a 1 in 18 dilution of venous blood. The patient was discharged after four weeks.

Six weeks after admission (May 21) the cyanosis had almost disappeared, although the sulphaemoglobin band was still detectable in a 1 in 12 dilution of the blood. Blood examination showed: Hb, 70% (Sahli); red cells, 4,800,000; white cells, 6,500 per c.mm. On June 11—i.e., just over eight weeks after withdrawal of the tablets—spectroscopic examination of the blood failed to reveal a sulphaemoglobin band. The general skin cyanosis had gone, but the lips were still dusky. Reviewing this case, we may conclude that the regular ingestion of phenacetin (8-20 gr. daily) over a period of two years had led to the formation of sulphaemoglobin in the blood.

Case II

A baker aged 57 was seen as an out-patient on July 10, 1943. He had had severe pain in the left shoulder during the previous three weeks. The onset of the pain had been sudden and some improvement had occurred with local counterirritant measures and analgesic powders. There was no dyspnoea.

The patient was a cheerful well-built man. Marked cyanosis, of blue-grey colour, was seen in the lips, face, ears, and especially in the nail-beds. Systemic examination did not show any further abnormality. In particular, there was no evidence of any upset of the respiratory and cardiovascular systems. Blood films were normal: Hb, 95% (Sahli); red cells, 4,250,000 per c.mm.; white cells, 7,800 per c.mm. The urine appeared to be normal on chemical examination. Rheumatic myalgia of the left deltoid muscle was found to be responsible for the pain; it responded to massage.

The analgesic powders prescribed by the patient's doctor contained 10 gr. of phenacetin and 5 gr. of acetanilide. Twelve powders were taken each week. Thus when first seen he had had a total of 240 gr. of phenacetin and 120 gr. of acetanilide in two weeks.

On being questioned he stated that the blue colour of his face had been noted by his relatives for a week and that it had caused them some concern, as they feared it was due to "heart trouble." The venous blood was darker than normal, having a chocolate tinge, and an absorption band in the red was found on spectroscopic examination. This band was not affected by potassium cyanide solution, and it was thought to be due to sulphaemoglobin. The band was easily detected in a 1 in 65 dilution of the blood.

No more powders were given, and the patient made an uninterrupted recovery. As is usual in sulphaemoglobinaemia, the cyanosis lifted slowly. Thus, one week later (July 17) cyanosis was still present and the sulphaemoglobin band was detected spectroscopically in a 1 in 30 dilution of venous blood. Two weeks later (July 24) the cyanosis was definitely less marked. The patient resumed his employment and did not return for further observation.

Both acetanilide and phenacetin had been taken in this case, and both may have contributed to the formation of the sulphaemoglobin. However, acetanilide, because of its greater toxicity, must be held largely responsible. No treatment of the cyanosis was given apart from withdrawal of the drugs. Long and Spriggs (1918) noted that inhalations of carbon dioxide and oxygen improved their cases of sulphaemoglobinaemia. Healy (1933) gave carbon dioxide and oxygen inhalations, together with a high-fat diet and ammonium chloride, to two cases of sulphaemoglobinaemia, and reported that the cyanosis disappeared within a week.

Discussion

Apart from the different drugs involved, these two cases of sulphaemoglobinaemia may be taken as examples of two clinical types in which cyanosis due to aniline antipyretics can occur. Case I is an example of the entity called "enterogenous cyanosis." The salient features here are psychological instability, weakness, chronic headache, and cyanosis without associated dyspnoea, occurring almost exclusively in women. While it is just possible that some of these cases may be idiopathic, it is now recognized that the majority are due to the ingestion of aniline antipyretics. The self-administration of drugs is often denied by these patients, and careful search may be necessary to find the actual cause of the sulphaemoglobinaemia. Case I suffered a relapse some months after dismissal. This patient was admitted to another hospital and a normal ventricular system was demonstrated by cisternal encephalography. She was then examined by a psychologist, who reported that the symptoms were psychological in origin. Case II presents many different features. Here the drugs were taken to obtain relief from pain caused by an organic condition. The pain of rheumatoid arthritis, as in the case reported by Coxon and Crawford (1940), or of rheumatic myalgia as in the case here described, may be the prime factor. Both sexes may be affected, psychological instability is not present, and the tendency to habit formation is not marked.

The mode of formation of sulphaemoglobin is the same whether it is produced by aniline itself or one of its derivatives. According to Snapper (1925), the circulating haemoglobin is sensitized by aniline derivatives and can thus unite with traces of sulphide absorbed from the intestine. Snapper induced sulphaemoglobinaemia in men by administering aniline compounds and sulphur. Outside the body, however, aniline and its related compounds have no effect on haemoglobin. It appears that aniline compounds are oxidized to the corresponding phenyl-hydroxyl amines and *p*-aminophenols in the blood stream and that these substances affect haemoglobin. Gley (1937) and Morgan and Anderson (1940) have demonstrated that both these substances, when added to blood, lead to the rapid formation of sulphaemoglobin if a trace of sulphide be present, and to methaemoglobin if sulphide be absent. Methaemoglobin can be produced only with difficulty by giving aniline antipyretics alone (Harrop and Waterfield, 1930). Further, methaemoglobin is highly unstable in the blood stream, being rapidly converted to haemoglobin (Stadie, 1921), and large quantities are required to produce cyanosis. Such cyanosis lifts within 24 to 48 hours after withdrawal of the drug, and is more likely to appear in acute than in chronic poisoning.

Finally, there is some evidence in favour of the view that coloured oxidation products of *p*-aminophenol are present in the blood after the ingestion of aniline compounds and that these are partly responsible for the cyanosis. Leslie (1939) described a case of acute acetanilide poisoning in which marked cyanosis was not associated with any change in the blood pigment and was considered to be due to the presence of some coloured derivative of acetanilide in the blood. Lundsteen, Meulengracht, and Rischel (1938) described 11 cases of chronic acetanilide poisoning with cyanosis, and were able to demonstrate a chocolate-coloured derivative of *p*-aminophenol in the blood of one of their cases which was specially investigated. It is difficult, at present, to assess the importance of this coloured *p*-aminophenol derivative in the production of cyanosis. In the majority of cases of chronic poisoning with aniline antipyretics, including the two described here, the cyanosis has been adequately, if not completely, accounted for by the presence of sulphaemoglobin in the blood.

Summary

The clinical and laboratory findings in two cases of sulphaemoglobinaemia due to aniline antipyretics are described. The method of formation of the abnormal pigment and other factors which may contribute to the cyanosis are discussed.

I wish to express my indebtedness to Dr. John Gracie for permission to investigate cases under his care, and to Drs. S. V. Telfer and G. H. Bell for their advice and help.

THE CHILD WITH FREQUENT COLDS

BY

D. H. IRWIN, M.B., Ch.B.
Medical Superintendent

AND

E. FRANKEL, M.D., M.R.C.P.
Physician

Essex County Hospital, Wanstead

In this article are given the results of a comprehensive investigation of 100 school-children suffering from frequent colds. At the invitation of the County Medical Officer, the children were referred by the school medical inspectors in the area of South-West Essex to a special clinic established at the hospital for the purpose of investigating this prevalent condition. The children were mostly drawn from middle-class and artisan families. The main part of the investigation consisted of clinical, *x*-ray, and laboratory examinations, and note was also taken of the environment and development of the children. While our chief purpose was to establish the clinical characteristics of the child with frequent colds, we also considered the problem of which department in a hospital should be responsible for their examination and should advise on their treatment.

It was inevitable that a number of children suffering from asthma and hay-fever should be referred to such a clinic. If these are excluded the history of the disorder is a typical one. The children usually began to suffer from frequent colds when they started attendance at school. They complained at first of blockage of the nasal passages followed by a mucous discharge which after a few days became muco-purulent. Often there was also a mild upper respiratory infection, with slight cough but little sputum. The general constitutional disturbances always found in an adult suffering from coryza were absent. The cold will last about two weeks, and then the child may be free for a few weeks until the next attack. This cycle will continue right through the winter and may often be present during the summer months, though the colds are usually less severe in the warm weather. In a small number of cases there was continuous muco-purulent nasal discharge between the attacks. Many of these children had had these frequent colds for as long as three years. While the children remain fairly well in spite of these frequent attacks, both the parents and the education authorities show concern at the amount of schooling lost. Some parents are also anxious lest the frequency of the attacks denotes some constitutional deficiency or even serious organic disease—e.g., tuberculosis.

We have examined 130 children, the findings in the first 100 of which are given below. There were 59 boys and 41 girls in this series. Four children were between the ages of 1 and 5, 69 between 6 and 10, and 27 between 11 and 15 years.

History

Their birth weights were all within normal limits, and they all developed normally from birth, reaching the usual milestones at the expected ages; 88 had been breast-fed and 12 bottle-fed; and 95 were given cod-liver oil and orange juice or other additional vitamins to supplement a normal diet. Only 2 children were in the habit of going to bed late. We analysed this series with regard to previous infectious diseases and found that 84 had had measles, 59 whooping-cough, 3 diphtheria, 59 bronchitis, 23 tonsillitis, and 14 otitis media. The majority of them had been vaccinated and immunized against diphtheria. No definite relation was found between any of these infectious diseases and the onset of colds. In 33 cases the mothers complained that their children snored at night and were mouth-breathers. Twenty-one children had had their tonsils and adenoids removed before being seen by us, mainly for the relief of frequent colds, and of these 18 were not improved. A near relative of 26 children had suffered from tuberculosis and of 22 from an allergic condition.

Clinical Examination

These children all showed normal weights and heights for their age and sex, and appeared to be well developed and of normal intelligence, with the exception of 3 who were slightly backward. None showed evidence of rickets. Their temperatures, pulse, and respiration rates were normal. Eight had carious teeth. Tonsillar enlargement of varying degrees was present in 39 and the adenoids were prominent in 27. In no case was there complete nasal obstruction, and the adenoid facies was rare. We specially observed the shape of the thorax of these children, and found that in 17 it was definitely barrel-shaped, in 5 alar, and normal in 78. In no case was serious lung disease found, but 8 showed a few scattered rhonchi and occasional rales. The heart, abdomen, and central nervous system were normal in all cases. No serious organic disease was therefore found on clinical examination.

Investigations

A number of laboratory tests were done on every child. The haemoglobin in 2 cases was between 60 and 70%, in 6 between 71 and 80%, in 45 between 81 and 90%, in 16 between 91 and 95%, and in 31 over 95%. The white count was between 6,000 and 10,000, and in no case was there a leucocytosis. The differential count showed some interesting features. Only 3 had increased eosinophils, but there were more than 40% of lymphocytes in 53 of the patients, showing a relative lymphocytosis. The urine was normal in every child. B.S.R. (Westergren) was done in one-third of the children, and was within normal limits. Twelve children had a positive Mantoux (1:1000), and 5 of these had positive family histories. None of them showed any other evidence of tuberculous infection, and there was no relation between the positive Mantoux reaction and anaemia or frequent colds. *X*-ray examination of their chests showed mild catarrhal changes in 49, particularly in the right lower zone, and also slight increase in the hilar markings. Skiagrams of their sinuses showed definite opacities in one or both maxillary antra in 51, and this was the most common abnormality found in the investigations done on these children. The radiographic appearances were thought to be due to mucosal swelling and thickening in the majority of cases, and only 3 showed opacities thought to be caused by actual pus in the sinuses.

Each child was also tested for allergic skin sensitivity to the common air-borne inhalants by the intradermal method, and to the pollens and the main food groups by the scratch test. In all, 14 groups covering 60 substances were used. No food sensitivity was discovered in any child. Eleven children showed positive reactions; 4 of these were cases of hay-fever and had marked sensitivity to pollens, and 5 were cases of bronchial asthma showing marked sensitivity to air-borne inhalants, those most frequently incriminated being house dust, feathers, horse dander, cat, dog, cow, wool, and furs, in that order. The remaining 2 cases gave positive skin reactions to air-borne inhalants, but the symptoms for which they had been referred were not regarded as allergic. The skin-testing was done independently of the history-taking and clinical examination, and therefore any bias in its interpretation can be excluded. It is interesting that in every case where an allergic factor was diagnosed it was confirmed by skin tests. At the clinic at this hospital for children suffering from respiratory allergy, in which skin sensitivity tests are done, 80% show positive reactions. This is in marked contrast to the present series, only 11% of which had positive skin reactions to the common air-borne inhalants. Two other features distinguishing the two groups are the absence of radiological abnormality of the nasal air sinuses in the allergic group and the low incidence of eosinophilia in the present series as opposed to the allergic.

The cervical, axillary, and inguinal groups of glands were carefully examined, and enlargement of the cervical chain of glands was noted in 30 cases. This was usually found in patients with enlarged septic tonsils. In addition, however, many children showed enlargement, sometimes to a considerable extent, of the other groups of lymph glands. This generalized glandular enlargement seems to be common in children who have an active septic or tuberculous focus, though often no obvious cause can be found. Twenty children with adenopathy had several additional investigations done to see whether further light could be thrown on this clinical problem—namely, the Paul–Bunnell test, Wassermann reaction, and biopsy of a small gland in 6 cases. All these tests proved negative, and the results of the routine investigations in no way differed from those obtained in children with no generalized glandular enlargement. The glands studied histologically showed activity only in the germinal centres, and the general structure of the gland was quite normal.

No bacteriological examination of the muco-purulent nasal discharge was made. Many workers have investigated its flora and the results are well known.

Conclusions

From these investigations we learn that the child with frequent colds is of normal development, build, and intelligence, and does not suffer from any other organic disease. Though minor degrees of anaemia occur, the children cannot be regarded as physically defective. The onset of the attacks at the beginning of school suggests that the continuous contact with infection is an important aetiological factor. No definite relation was found between the colds and developmental abnormalities, upbringing, previous illnesses, or contact with tuberculous infection. No conclusion can be drawn from the lack of improvement after tonsillectomy, as naturally the children who improved after this operation would not be sent to the clinic; but we believe that in the absence of other indications, such as infection of the tonsils or nasal obstruction due to adenoids, surgical removal of the tonsils and adenoids will be relatively ineffective as a measure designed to prevent frequent colds. No allergic aetiological factor could be established. Investigation of the blood, the Mantoux test, and special investigations with regard to glandular enlargement, though of general interest, did not throw any light on this condition. These frequent colds are due to inflammatory reactions of the mucous membrane lining the nasal passages and air sinuses, and give rise to few general constitutional disturbances in children. A filterable air-borne virus seems to be responsible, aided by other organisms such as the pneumococcus, *Str. viridans* and *haemolyticus*, staphylococcus, *Micrococcus catarrhalis*, or *Haemophilus influenzae*, which set up secondary infection. Repeated colds may cause nasal obstruction, and there may be arrest of nasal development and failure of muscular control over nasal respiration. These factors predispose the child to further infection.

We think that the treatment of this condition is entirely a problem for the ear-nose-and-throat surgeon, who should keep these children under supervision in a special clinic where they can receive conservative and operative treatment. A general medical or surgical, paediatric, or allergic clinic should not have to deal with these children, as, apart from the local conditions affecting the nasal passages, sinuses, and throat, no other abnormality could be discovered.

We wish to acknowledge our indebtedness to the County Medical Officer, Dr. W. A. Bullough, for his interest and co-operation in the investigation, and for permission to publish the results.

Dr. Douglas Lothian, resident medical superintendent of the Down Mental Hospital, Downpatrick, in his report for 1944 records that 39 patients were treated by the electro-convulsive method during the year, and 9 of them were discharged recovered, 3 being cases of dementia praecox and 6 suffering from depression. Two other cases of depression made such considerable improvement as to warrant the expectation that they would soon be discharged, as did 1 case of dementia praecox. Three cases of dementia praecox made an apparent recovery, but relapsed later; 2 cases made some improvement, but relapsed completely later. Forty-seven patients recovered without electro-convulsive therapy, but with psychotherapy and occupational therapy; these included 18 cases of dementia praecox, 16 depressions, 7 anxiety neuroses, 5 manias, and 1 paraphrenia. The other recoveries included a case of general paralysis of the insane treated by tryparsamide and bismuth, 2 cases of arteriosclerotic confusion cleared up by careful attention to living habits, 1 case of uraemic confusion, and 2 cases of mental disorder resulting from alcoholism.

MASS MINIATURE RADIOGRAPHY OF FACTORY GROUPS IN MIDDLESEX

BY

W. POINTON DICK, M.R.C.S., L.R.C.P.

Physician to the M.C.C. Mass X-ray Unit

The Middlesex County Council Mass Radiography Unit took *x*-ray films of its first volunteer on Oct. 11, 1943, and to July, 1945, had examined over 70,000 persons, their ages ranging from 12 to 76 years. This report is confined to a survey of the work of the unit during the year 1944, with the exception of the age groupings of examinees and significant lesions, which are for the period Oct., 1943, to June, 1944. During 1944 ten factories were visited, their population ranging from 1,050 to 4,608. Neighbouring factories were invited to attend at most of these centres, so that the actual number of examinees varied between 706 and 9,640. Using the present set-up and the routine to be described below, it has been found to be uneconomic, from the point of view of time, to visit groups of fewer than 3,000. The response varied between 73 and 93% for inside groups, but fell to as low as 36% for some of the visiting factories. This was readily accounted for by the extra loss of working time when any considerable journey had to be made. The average period away from the work for an "inside" examinee was 15 minutes, and the unit has received letters from several firms stating that there was no appreciable loss in production time during its visit to their factory.

In a normal working week miniature films are taken on Monday, Tuesday, and Wednesday, and large films on Thursday. Friday is devoted to viewing miniatures, reporting on large films, and general clerical work. An average of 450 to 500 miniature films are taken daily, and as 500 is the maximum that can be satisfactorily viewed at any one sitting it is necessary to hold three viewing sessions weekly. During the first week of a visit there are four full days for miniatures, making a weekly total of 1,800 to 2,000, and the viewing sessions are correspondingly increased.

On Friday is completed the list of those persons required to attend for large films on the following Thursday. At one time it was the practice to send out the recall letters to their home addresses. In order to be sure of their receiving them in time it was necessary to post the letters a few days before the examinees were required to attend. We found that this period of waiting caused considerable anxiety and the development of not a few symptoms. To obviate this, examinees are now notified, where possible, by a note handed to them at their work an hour or so before their large film is due to be taken. Finally all persons who have a large film have a medical interview, including a discussion on their wet film, shortly after it is taken. In this way, by the time they return home from their work the whole procedure is completed.

Analysis of Results

The total number of examinees during 1944 was 34,227, comprising 19,609 males and 14,618 females. It has been impossible to date to set these out in age groups, but this has been done for the 20,982 persons examined by the unit during the period Oct., 1943, to June, 1944, and these are shown in Table I.

TABLE I.—*Age Groups of Examinees*

Age:	14–24	25–34	35–44	45–54	55+	Total All Ages
M ..	1,758* (14·6%)	3,658 (30·4%)	4,262 (35·5%)	1,610 (13·4%)	722 (6·0%)	12,010
F ..	3,680 (41·0%)	2,711 (30·2%)	1,718 (19·1%)	695 (7·7%)	168 (1·9%)	8,972

* It may be noted in regard to the small number in this group that in a paper by Trail *et al.* (1944) reporting a survey in the Royal Air Force 70% of the male examinees were in the 17–24 age group and that the incidence of active pulmonary tuberculosis among them was 0·3%.

Refusals.—It was possible to analyse the refusals by 682 persons from two factories with a total available population of 5,930. The result is given in Table II.

TABLE II.—*Analysis of Refusals by 682 Persons*

Age	Men		Women	
	Available	Refusals	Available	Refusals
14–34 ..	1,177	67 (5·7%)	2,167	165 (7·6%)
35+ ..	1,469	260 (17·7%)	1,117	190 (17·0%)

A further factory (Factory A of the Medical Research Council Report on Mass Radiography of Civilians) has been visited at yearly intervals, first by the M.R.C. and subsequently by this unit. It is of interest that out of 148 persons at this factory who refused in 1943 but were *x*-rayed in 1944, and a further 214 who while refusing in 1944 attended for examination in 1945, there was not one who showed any evidence of pulmonary tuberculosis.

There were 1,909 examinees recalled for a large film in 1944, giving a recall figure of 5.6%. Of these, 50—that is, 2.6% of those recalled—did not attend for their large film. As would be expected, the number of defaulters was always higher in the outside groups, averaging 3.7%, compared with 1.6% for the main factories. There were a further 36 who, having had a large film and on interview been recommended to attend a chest clinic, failed to do so. Of those who attended a chest clinic 1.5% were reported as requiring no further action.

Abnormalities Found

The abnormalities discovered among the 34,227 persons examined by the unit during 1944 are listed below. They are divided into tuberculous and non-tuberculous groupings. Cardiovascular lesions predominated in the latter, and it is of considerable interest that the great majority of these patients were already aware of their disability.

A. Non-tuberculous Pathological Conditions

Cardiovascular	157 (0·5%)
Congenital 12; acquired 145 (86% already knew of their condition)	
Tumours	15
Bronchiectasis	31
Lung abscess	2
Pneumoconiosis	33
Pneumonitis	10
Bronchitis and emphysema	104
Pleural thickening	569*
Miscellaneous	158

* Some of these were almost certainly of tuberculous origin.

B. With Evidence of Pulmonary Tuberculosis, including Healed Lesions (1,435 Cases)

(1) Known cases	140
(Improved or no change, 130; relapsed, 10)	
(2) Newly discovered:	
(*a*) Requiring no further action	861 (2·5%)
(Including 537 healed primaries)	
(*b*) Showing significant lesions	434 (1·3%)

C. Analysis of Significant Lesions

(*a*) Extent of disease:	
Unilateral	275 (63·4%)
Bilateral	159 (36·6%)
(*b*) Disposal:	
Observation	346 (1·0%)
10·8% of these were put on modified work	
Treatment	88 (0·3%)

(*c*) Presence of symptoms (Table III):

TABLE III

Disposal	With Symptoms	Symptom-free	Total
Observation	105 (32·0%)	241 (68·0%)	346
Treatment	46 (52·3%)	42 (47·7%)	88

(*d*) Sputum results in the 88 treatment cases:

None	34
Negative	32
Positive	22

(*e*) Age groups of significant lesions found in first 20,982 examinees (Oct., 1943–June 12, 1944) (Table IV):

TABLE IV

Age:	14–24	25–34	35–44	45–54	55+	Total All Ages
M ..	14 (0·8%)	40 (1·1%)	59 (1·4%)	27 (1·7%)	8 (1·1%)	148 (1·2%)
F ..	42 (1·1%)	38 (1·4%)	20 (1·2%)	6 (0·9%)	1 (0·6%)	107 (1·2%)

Comments

If the population of Middlesex be taken as 2,000,000 it can be calculated that there are approximately 1,200,000 persons in the 14–55 age group. Allowing that the age distribution of the females in the above survey is very skew, being excessively overweighted at ages 14–24; it appears that there are probably some 3,000 undiagnosed cases of pulmonary tuberculosis in the county in need of treatment, and that half of these cases are without symptoms.

A CASE OF LEFT-SIDED APPENDICITIS

BY

J. W. L. HADDON, M.B., Ch.B.

Resident Surgical Officer, Beckett Hospital, Barnsley

Although left-sided appendix is by no means rare, the following case is interesting in that a full examination was possible later in the post-mortem room and an unusual condition found.

Case Report

A soldier aged 19, three months convalescent from a subtotal thyroidectomy for Graves's disease, was admitted to hospital on March 21, 1945. He was in a very nervous and toxic state, and gave a history of severe abdominal pain, which had started suddenly 36 hours previously and become progressively worse. The pain was continuous in character, and was at first generalized and was accompanied by nausea, but had since become localized to the hypogastrium and medial side of the right iliac fossa; he had vomited twice just before admission. There was no history of dysuria, and the bowel actions had been normal. Previous history did not give any indication of gastro-intestinal disease.

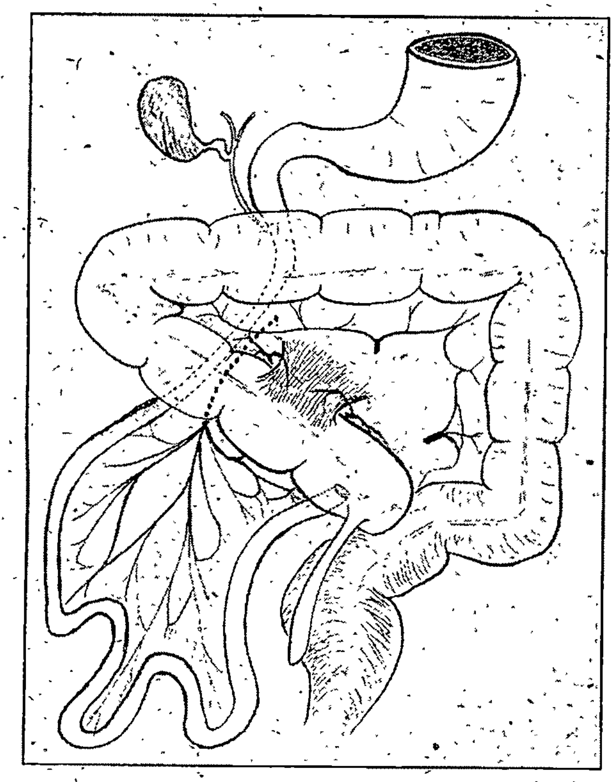

Diagram showing the abnormal position of the abdominal viscera, with the restrictive band.

Abdominal examination showed slight distension, with rigidity over the whole lower half of the abdomen; and acute tenderness localized to the hypogastrium and right iliac region. Auscultation revealed a "silent abdomen." Per rectum, he was tender anteriorly, high up. His general state was poor, with dehydration and a rapid pulse which showed occasional extrasystoles. A diagnosis of early diffuse peritonitis, secondary to a perforated inflamed appendix, was made, and operation arranged accordingly.

Operation.—The abdomen was opened through a right gridiron incision as there was no clinical indication of an abnormal situation of the appendix, and purulent fluid escaped. On inspection neither the appendix nor the caecum could be seen, and their absence was confirmed by finger exploration—the right iliac fossa being apparently filled with distended coils of small gut only. The incision was closed and replaced by a right lower paramedian incision; this revealed a long gangrenous appendix lying obliquely across the left lower abdomen, from left to right, with the tip reaching the recto-vesical pouch. The caecum was occupying the left iliac fossa, together with the sigmoid colon, and it was ascertained that the liver was in its normal situation; but, apart from this, no further exploration was attempted, in view of the patient's critical state, and appendicectomy with suprapubic pelvic drainage was carried out. Intravenous infusion was started, and an attempt was made to institute continuous duodenal suction; but the man proved most intractable and refused to tolerate either form of treatment, repeatedly pulling out both Ryle's tube and intravenous cannulae.

He became progressively worse, developing paralytic ileus and dying on the fifth day. Permission for a "limited" necropsy was granted.

Post-mortem Findings.—On opening the abdomen the small bowel was found to be entirely confined to the right side, with the caecum and ascending and descending colons occupying the left. The ascending colon passed obliquely upwards and to the right to join the transverse colon at a normally situated hepatic flexure, the ascending colon being maintained in its abnormal site by a thick band, 2½ in. broad, between its middle third on the left side and the transverse mesocolon. The appendix arose from the right side of the caecum, and the ileum entered it towards the right side on its postero-lateral aspect. The jejunum started at its junction with a vertically descending third part of the duodenum, on the right-hand side of the superior mesenteric artery. No other congenital abnormalities were found. (See Diagram.)

Commentary

I could not find any evidence of inflammatory adhesions, and there were no enlarged or calcified mesenteric glands, so it must be presumed that the band from the ascending colon was of congenital origin; further close inspection of the band showed fairly large vessels coursing in its substance, derived from the right colic artery and distributed to the colon, suggesting that it was a contracted right mesocolon.

A so-called "wandering caecum," due to excessive rotation of an unduly mobile caecum, was excluded by the position of the appendix and ileo-caecal valve on its right side; and further proof of the congenital origin of the condition was supplied by the abnormal site of the duodeno-jejunal flexure to the right of the superior mesenteric artery.

From these findings it is suggested that the case described is a failure of rotation of the mid-gut loop, which normally takes place at the beginning of the tenth week of foetal life during the process of reduction of the "physiological umbilical hernia"; the colon and caecum, with the attached post-arterial mesentery, being allowed to enter the abdominal cavity first, instead of the normal mid-gut and pre-arterial mesentery—probably as a result of a lax umbilical ring. As a result of this mechanism, the later return of the mid-gut loop tends to displace the vitelline artery and hind-gut, with its post-arterial mesentery, to the left and dorsally, thus accounting for the left-sided position of the large bowel. Some attempt at normal fixation of the mesenteries had taken place, as is shown by the hepatic flexure occupying its normal position, in contradistinction to the more usual U-shaped transverse colon of non-rotation of the mid-gut loop, and this partial fixation probably prevented the marked tendency to volvulus around the superior mesenteric pedicle in early infancy, of which Dott describes two cases (*Brit. J. Surg.*, 1923, **11**, 251).

An unusual feature of the clinical findings was the presence of signs and symptoms in the right iliac fossa, at a point remote from the actual position of the appendix; but its deep pelvic situation might have accounted for this.

I am indebted to Dr. Ponder, county medical officer for Kent, and Mr. J. W. D. Buttery, medical superintendent of the Royal Victoria Hospital, Folkestone, for permission to publish this case.

A. Louis (*Thèse Paris*, 1945, No. 98), who records an illustrative case in a girl aged 19 months, came to the conclusion that the best treatment of Still's disease at the present time consists in intramuscular injection of gold salts.

Medical Memoranda

Four Cases of Hemicolectomy

Below are presented accounts of four cases of hemicolectomy performed for different and rare conditions.

Case Reports

Case 1.—Man aged 56. On admission the patient gave a history of increasing constipation for the past six months, together with colicky abdominal pain about seven hours after meals, loss of weight (one stone), and recent onset of vomiting after meals. On examination a palpable mass was felt occupying the right iliac fossa and right hypochondrium, which was not tender, but which was fixed to the posterior abdomen. *Operation.*—Heavy spinal anaesthesia. A plasma drip was started and a transverse muscle-cutting incision made. On exploring the abdomen an ileo-colic intussusception was found, extending as far as the middle of the transverse colon. It was possible to reduce the intussusception only up to the hepatic flexure, so it was decided to undertake a hemicolectomy, removing the terminal ileum, caecum, ascending colon, and hepatic flexure, and performing an ileotransversostomy. The patient made an uninterrupted recovery. The cause of the intussusception was a lymphosarcoma of the terminal ileum.

Case 2.—A woman aged 70. This patient was admitted as an emergency case (? acute appendicitis). She had complained of colicky abdominal pain in the umbilical region for the past eight hours and also of pain in the right iliac fossa. A history of a similar attack two months before was given. The temperature was 99° and the pulse 74. On examination a mass about the size of a hen's egg was palpable through the abdominal wall. *Operation.*—Heavy spinal anaesthesia. A plasma drip was started and a transverse muscle-splitting incision made. On exploring the abdomen an appendix 4 in. long, thickened and hard, was found. This thickening and hardness extended to about a third of the caecum. A diagnosis of carcinoma of the appendix was made, and a hemicolectomy was performed. The terminal ileum, caecum, ascending colon, and hepatic flexure were removed and an ileotransversostomy was done. The patient made an uninterrupted recovery, except for an intramural abscess which developed at the outer part of the incision. On microscopical section an adenocarcinoma involving the appendix and extending into the caecum was found.

Case 3.—This patient, a woman aged 60, was admitted as an emergency case with a two-days history of central abdominal pain, colicky in type, and vomiting which began about two hours after onset of pain. This vomiting was not marked until just before admission to hospital. The bowels had moved on the day of the onset of abdominal pain, but had only a slight motion the next day; thereafter neither faeces nor flatus was passed. On examination the lower abdomen was distended, chiefly in the right iliac fossa; there was also tenderness over the lower abdomen. On auscultation peristalsis was increased; the general condition was good. *Operation.*—Heavy spinal anaesthesia. Plasma drip started. A right paramedian subumbilical incision was made, the caecum immediately presenting itself, greatly distended, black, and friable. The lower half of the ascending colon was also involved; the caecum and ascending colon had twisted anti-clockwise on the mesentery. The volvulus was apparently caused by a very long mesentery to the right colon. As the general condition was good, it was decided to carry out a hemicolectomy; the ileum, caecum, ascending colon, and hepatic flexure were removed and an ileotransversostomy was performed. The patient made an uninterrupted recovery.

Case 4.—A man aged 62. This patient was admitted as an emergency case with a two-days history of lower abdominal pain, colicky in nature, and vomiting soon after. On the day of admission vomiting (dark brown in type) had been continuous. He had been costive since the onset of abdominal pain and had passed neither flatus nor faeces on the day of admission. On examination the lower abdomen was distended (most markedly in the right iliac area) and was tympanic on percussion; there was also lower abdominal tenderness. On auscultation peristalsis was increased. Blood pressure was 110/82. *Operation.*—Cyclopropane anaesthesia. A plasma drip was started immediately. A right paramedian incision was made; there was volvulus of the caecum and the proximal half of the ascending colon, non-viable, friable, and blue-black in colour. A hemicolectomy was performed, removing the terminal ileum, caecum, ascending colon, and hepatic flexure, and ileotransversostomy was carried out. The patient developed pneumonia and died three days after operation.

Hugh MacCarthy, F.R.C.S.I.&Ed., M.R.C.P.I.

Allergy to Egg-prepared Vaccines

A case is here reported of an alarming reaction to the egg allergen in typhus vaccine. One previous case has been found in the literature, and more examples of similar reactions to preparations from egg media may be expected. Oral desensitization for six months enabled this patient to take 60,000 times the dose of allergen originally causing symptoms and to eat eggs with impunity. But skin tests were unchanged, and it would have been dangerous to attempt further inoculations. A simple precaution before giving injections of such vaccines would be to ask the question, " Do you eat eggs?".

Case Record

In Nov., 1943, an airman was admitted to No. 1 N.Z. General Hospital, Middle East Forces, in a state of severe collapse, having vomited blood and become acutely breathless and then comatose. He had an urticarial eruption and his respiration was asthmatic. By next morning he had completely recovered. He had been allergic to eggs all his life—35 years—and was usually able to avoid egg foods by their taste. But if he happened to swallow the food he would vomit, or, if there was no vomiting, he would get oedema of the lips, tongue, and larynx, asthma, urticaria, and general shock. He had never before vomited blood or passed into coma, and as he was at a meal when the symptoms came on he concluded that the rissoles contained egg. Further inquiry, however, showed that he had had his first antityphus inoculation 15 minutes before this meal. It was then clear that his reaction was due to the introduction of a large amount of egg protein parenterally. An extract of egg was made, and strongly positive scratch tests were obtained both in the patient and in a subject passively sensitized by his serum.

Oral desensitization was then started, daily doses being given of a quarter of a teaspoonful of a 1: 2,500 dilution of egg in water. At first this caused a mild reaction in the form of nausea and tingling of the lips, which lasted about half an hour. This reaction passed off in a few days, and the dose was increased by 50%. With a steady increase in this manner he continued the treatment until in July, 1944, he reached the dose of one raw egg daily, which has been continued since. On two occasions the sensitivity has shown signs of returning—once with a nasal cold and once when he stopped treatment for a few days.

In Sept., 1944, further scratch tests were made with egg extract and with undiluted typhus vaccine. Both gave strong reactions (3 plus), of no less intensity than before desensitization.

Discussion

The preparation of vaccines from viruses and rickettsiae on egg media is a recent method of which more and more examples will be seen in the future. And since a small section of the population are highly allergic to egg protein, this will lead to some severe or even fatal reactions.

For the following list of vaccines prepared on egg media and manufactured on a commercial scale I am indebted to Major E. C. Van Rooyen, R.A.M.C.

Typhus	Prepared from yolk sac
Yellow fever	" " egg embryo
Influenza	" " " "
Smallpox egg-lymph	" " allantois

An alarming reaction from the egg allergen in yellow-fever vaccine has already been reported by Swartz (1943), his patient developing asthma, gastro-intestinal allergy, and angioneurotic oedema a few minutes after the injection. My own patient gave a history of receiving yellow-fever inoculations without any ill effects, and apparently his sensitivity was to a yolk allergen not present in egg embryo.

The response to desensitization is in keeping with atopic sensitivities in general. At the outset the airman was sensitive to even the minute quantities of egg protein which could get into his circulation without being digested. Prolonged desensitization enabled him to take these minute amounts with impunity, but not the relatively large doses introduced by injection or scratch test.

I wish to thank Brig. H. S. Kenrick, C.B.E., E.D., N.Z.M.C., Director of Medical Services, N.Z.E.F., for permission to publish this report.

Swartz, H. (1943). *J. Lab. clin. Med.*, 28, 1663 (quoted in editorial, *J. Allergy*, 1944, 15, 241).

The 25th report of the National Council for the Unmarried Mother and her Child (117, Piccadilly, W.1) has a foreword by the president, Lord Gorell, and is signed by the chairman, Mrs. H. A. L. Fisher, to whose devoted labours he pays tribute. The report covers a period of fifteen months and is a record of strenuous, unremitting, and valuable work. Before long the Council hopes to become incorporated and enter upon a new stage of its existence. Meanwhile it has become affiliated to the National Council of Social Service while renewing affiliation to the National Council of Women and remaining a constituent body of the National Council for Maternity and Child Welfare. The Case Committee has dealt with an unprecedented number of cases, and the Ministry of Health's scheme for the care of women discharged from the Services on account of pregnancy has involved the Council in a very great deal of work. While the Council is not itself responsible for any home, nearly all the homes and hostels of the voluntary and statutory organizations are affiliated to it.

Reviews

WAR AND SOCIAL PSYCHIATRY

The Shaping of Psychiatry by War. By John Rawlings Rees, M.D. (Pp. 158. 10s. 6d.) London: Chapman and Hall. 1945.

Brigadier Rees, as consulting psychiatrist to the British Army, has had a unique opportunity of investigating the psychiatry of the war, which he has summarized in these Salmon lectures given in America. While he has for the most part described the work of others, he has himself been the inspiration of that work, and as such has, with the whole body of psychiatrists, Service and lay, changed the "shape" of psychiatry. The main problem of modern psychiatry is concerned not with the psychoses but with the numerous personality problems which, in certain adverse situations of work and of social environment, lead to the psychoneuroses and behaviour disorders. Methods of analytic treatment are necessarily prolonged and can, therefore, deal with only a small proportion of those who need such treatment. An effort must therefore be made to prevent even those who are predisposed from breaking down. This is the aim of social psychiatry, and the principles and means of coping with this problem in the Army have here been described. It opens up vast possibilities for civilian life in the future.

The "priorities" in social psychiatry are: first, methods of selecting the right man for the right job; secondly, prophylaxis by better training and "man management"; thirdly, morale; and, finally, treatment. The first three are fully dealt with and their methods described.

Selection.—Some points make very interesting reading; for instance, when all candidates are examined by the psychiatrist they welcome it, whereas if some only are selected for examination this implies that they are peculiar, and they dislike it. Brigadier Rees considers that the chief credential of a good psychiatrist is the personality qualification. The importance of personality qualifications is indicated in the fact that a much shorter course is required to make a good psychiatrist provided he is of the right personality. This applies also to the selection of officers: "It was early realized that in selecting men for commissioned rank the personality factor was the major consideration, provided that the candidate had adequate intelligence" (p. 72). But is personality a "factor"? Is it not the sum total of factors, of which intelligence is one? One nevertheless has an uncomfortable feeling that in assessing personality we are assessing something the nature of which is not understood or defined. For selection, the tendency has been away from laboratory tests to tests calling forth the whole personality, such as putting the officer into a difficult test situation with a number of his fellows without any instructions.

Prophylaxis.—While the author rightly stresses that those with analytic experience are the best capable of designing methods and carrying out these procedures, it is not perhaps sufficiently stressed that only by the radical investigation and treatment of the individual can the predisposing causes be rightly assessed and the prophylaxis become really effective. Without this, social psychiatry will become a superficial study and make blunders. The medical officer, says the author, has to think in terms of groups rather than of individual patients. This is true for prophylaxis, but it is not exclusively true of treatment; and it is to be questioned why the individual casualty suffering from a war neurosis should not receive the same care, say, as an orthopaedic patient, who sometimes takes months to recover.

Morale.—To many this will be the most interesting part of the work: for instance, the observations on the danger of discipline without morale. "The three main factors which make for good morale in wartime are: adequate war aim and purpose, a sense of one's competence and value, and the feeling that one matters as an individual in a group of other similar people" (p. 84). Some of these investigations confirm earlier opinions, but others gave unexpected results, such as that women (A.T.S.) in mixed batteries complained more of fear of sterility than of sex (possibly because fear inhibits sex), and that sexual disorders arose out of loneliness rather than excess of sex feeling. A hint from child psychology was found to apply also to Army recruits (p. 79)—namely, that it is best to let a recruit use his weapon first and then learn to look after it, otherwise he loses the enthusiasm with which he started and becomes bored. Some of us wondered at the beginning of the war whether a war could be successfully fought without hate. An interesting observation regarding morale is, therefore, that the original attempt to inculcate hate of the enemy was ineffective and led to depression; also that too much realism at first encouraged anxiety. The recruit had to be inoculated into realism. The importance of morale in war has always been recognized, but never so much as in this war. On page 95 Brigadier Rees states: "Wars are won, not by killing one's opponents, but by undermining their morale." But some of us may still believe that killing them is the most effective way of undermining their morale.

In the chapter "The Way Ahead" Brigadier Rees points out the application of the findings in war psychiatry to social psychiatry in civil life. These are but some samples of the large number of interesting subjects dealt with. Altogether it is a book that everyone interested in psychiatry, and in social and industrial medicine, should read. It gives a new orientation to the practice of psychiatry, and Brigadier Rees deserves the thanks of the profession for so lucid and interesting an introduction to the subject.

HISTORY OF ANAESTHESIA

The History of Surgical Anesthesia. By Thomas E. Keys. With an introductory essay by Chauncey D. Leake, and a concluding chapter by Noel A. Gillespie. (Pp. 191; illustrated. $6.00.) New York: Schuman's.

The serious study of the origins and development of a specialty augurs well for that specialty. Sturdy and well-cared-for roots can but ensure a healthy and productive tree. So far as anaesthesia is concerned an accurate and scholarly account of its history has been long overdue. The earlier appearance of such a history might have prevented both the duplication of invention and the undeserved praise for the supposed originality of the inventors.

Major Keys has obviously put enthusiasm and energy into his task and has managed to pack a remarkable amount of information into small compass. No anaesthetist will read this book without pride, nor surgeons without wonder that so much has been accomplished in the field of anaesthesia in so short a time. The emphasis on American achievement is a little heavy, and British anaesthetists may feel that the very noteworthy contribution of this country to the development of inhalation anaesthesia in the 19th century is treated rather cursorily. One of the many lessons to be learnt from reading this book is that progress in anaesthesia is not to be made by a new knob here or an altered tap there. Such stories as that of divinyl ether, told by Chauncey Leake in the introductory essay, are examples to inspire those who would make real contributions to the subject.

Major Keys has made his material not only readable but enjoyable both to the medical and to the interested lay reader. For the anaesthetist, however, the book cannot be regarded as the last word on the subject. There are only some 90 pages of text, the other half of the book consisting of a chronology, lists of references, and an index. Included, also, is a short and excellent essay by Dr. Gillespie on the future of anaesthesia. Inevitably, therefore, much has had to be omitted. Thus no reference is made to Cattlin, whose revolutionary introduction, in 1868, of a reservoir bag, now frequently misnamed a rebreathing bag, made it possible to dispense with the cumbersome gasometer. Clover, an illustrious pioneer in this country, receives but five lines in the text, in none of which are even mentioned his more important contributions, such as the, to us, familiar ether inhaler and the very ingenious and accurate apparatus for the production and administration of known percentages of chloroform. They receive a bare mention in the chronology. Some of the sources might not satisfy the academic, who would dispute the superiority of an encyclopaedia over an author's own works as to what the author did or did not say.

Most of the illustrations are portraits, and but few are instructive or help to clarify the text. They provide, however, a fine picture gallery of Americans, past and present, whose names are respected in anaesthesia. Queen Victoria finds herself in strange company. Her patronage of and submission to anaesthesia *à la reine* seem little qualification for inclusion of her portrait here.

However, these are but small blemishes in an excellent little book. One hopes that it will be widely read and become a pioneer, to be followed by more exhaustive works on this subject, which will provide not only interest for the clinician but also a detailed source of reference for the research worker in anaesthetics.

COSMETICS

Modern Cosmeticology. By Ralph G. Harry, F.R.I.C. Second edition. (Pp. 432; illustrated. 35s.) London: Leonard Hill Ltd. 1944.

This book had a very good reception when first published in 1939. There are considerable alterations in the new edition. The book has grown very greatly, having expanded from fewer than 300 to over 400 pages, and is now embellished with numerous figures, including 8 coloured plates. It may be added that, whereas it was originally published in New York, it has crossed the ocean, notwithstanding the difficulties of war, and is now published in London. Although it has greatly increased in size the paper used is much thinner, and it has diminished in bulk and is very convenient to handle.

The new edition is fortified by a foreword from Dr. P. B. Mumford, who gives it his blessing. The scientific approach to the whole subject, which we noted with satisfaction in the first edition, is still well maintained—perhaps this is in large measure due to the fact that Mr. Harry is an original investigator of some experience. He himself has worked particularly on the conditions necessary for the preservation of oils. These compounds are of much importance in the manufacture of many forms of cosmetics, and they are very liable to become rancid owing to the development of a certain degree of oxidation in them, and rancidity spoils any cosmetic preparation. This tendency can be controlled to a very large extent by the help which certain anti-oxidants give to the keeping qualities of various oils. His experiments show that gum guaiacum is a very good anti-oxidant which has the advantage that, unlike several other compounds that have been used for the purpose, it appears to be quite innocuous.

This volume includes a consideration not only of creams and powders but also of the cosmetic problems presented by the hair, the teeth, the nails, and, in fact, by all the cutaneous appendages. Naturally it overlaps the domain of the skin physician, but the author is extremely careful not to trespass too far into pathology and therapeutics, and there is no doubt that the dermatologist can profit a great deal from study of this book; in fact, even more from the present edition than from the original one. On the whole the illustrations are apposite and useful, but it is doubtful whether the coloured photomicrographs of the human skin and scalp are valuable enough to justify the additional cost they must involve. They throw very little light upon the problems with which cosmetics are concerned. This, however, is a very minor blemish, if indeed a blemish at all, and we have no hesitation in recommending *Modern Cosmeticology* to all concerned with the enhancement of human beauty.

Notes on Books

Dr. **Arlette Barbequot-Butavand** has produced a book—*Cahiers de Dessins d'Anatomie*—for the use of the hospital attendants and nursing staff of the Medical School at Lyons. It is issued by J. B. Baillière et Fils, of Paris, in two parts, each containing 57 plates and comprising 203 separate figures. These consist of a series of anatomical drawings in simple outline, with brief legends and names of the principal parts, supplemented by occasional comments. The drawings are arranged in copybook form, the plates being on one side of the opened book—the left—whereas the opposite page on the right is left blank, to be filled in by the pupil with notes or copies of the printed drawings, which it is suggested may be coloured so as to distinguish bones, arteries, veins, nerves, and muscles from one another. The principal object which the author has had in mind is, he states, twofold: since anatomy is easily understood and impressed on the memory by drawings, to provide something concrete which will enable each pupil to develop his own powers of observation and dexterity in drawing; and at the same time to cultivate his visual memory. He also recommends that pupils should, when possible, supplement the drawings on the printed page by original drawings from Nature, and thus increase the value of their course of study and of the books they read and benefit them in the exercise of their profession. In these days, when hospital attendants, nurses, and doctors of different nationalities frequently become associated in their work, the publication of these two "Cahiers" should be no bar to their use by English-speaking readers, but, on the contrary, a distinct advantage, since it would tend to familiarize them with the names of the various parts and organs of the body in the French language.

The importance of the care and housing of the aged is being increasingly realized. A pamphlet entitled *Bucks Old People's Welfare* tells the story of the formation of a county committee for that purpose at Aylesbury on Feb. 3, 1945. Sir Leonard West, chairman of the Buckinghamshire County Council, presided, and every branch of social endeavour was represented. It was pointed out by Mrs. Keeling that it was the transfer of responsibility for supplementary pensions in December, 1940, to the Assistance Board that had brought to light the fact that many old people were living alone under the most unfavourable conditions. The aim of this committee was to see that such were not only fed, clothed, and sheltered "in a negative kind of peace" but enabled to spend what was left of their lives in "positive happiness." In pursuit of this laudable, if difficult, objective, representatives were appointed to look into the situation and to report later with suggestions to an adjourned conference. The body of this booklet discusses, in an interesting way, both short-term and long-term policy for remedying a gap in our social services still inadequately filled, though some real success has been achieved already. It is evidently written by an enthusiast for the subject, with definite and clear-cut ideas. Copies may be had from the printers, Hunt, Barnard and Co., Aylesbury, price 1s. 2d. post free.

The welcome we gave to the first edition of Dr. **Julius Bauer**'s *Constitution and Disease* can be given with equal cordiality to the second (William Heinemann; 21s.). That this has been called for within eighteen months of the publication of the original edition proves its usefulness. For too long the genetic factor in disease received scanty and intermittent attention, and although this is being corrected it has not been easy to obtain the evidence in a compact form such as is now possible from these pages. In this new edition the text has been amplified, the bibliography has been added to considerably, and it is now, as it should be, provided with an adequate index.

We have noticed in these columns several books on the population problem. Mr. **Mark Abrams**'s little book, *The Population of Great Britain: Current Trends and Future Problems* (George Allen and Unwin; 3s. 6d.) is among the best; it is very clearly written and objective. It can be read through in an hour and provides any intelligent person with an adequate basis of knowledge. We may add that, unlike so many wartime books, it is pleasant to look at and read.

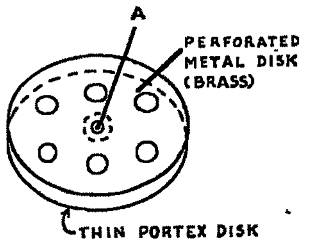
Preparations and Appliances

VALVE DISK FOR CIRCLE ABSORBERS

Dr. J. **Clutton-Brock** (Lincoln) sends the following description of a new valve disk for circle absorbers:

This device consists of a disk of thin flexible portex joined concentrically to a thin perforated disk of metal.

I have found these disks very satisfactory in my absorber as they only weigh 13 gr. as opposed to 34 gr. for a standard metal disk of the same size. There is no tendency to blow back at a pressure of 200 mm. Hg. Although they are, perhaps, a little heavier than a similar bakelite disk, there is no question of warping, and I have found most bakelite disks definitely not very flat. The two disks are joined together at the point A by a small aluminium rivet. The thickness of the metal disk is 0.005 in., and the portex 0.007 in. The thin portex disk lies on the knife edges and makes a perfect airtight seal.



SULPHATHIAZOLE SUSPENSION

Messrs. Menley and James, Ltd., now offer for sale "mickraform" sulphathiazole suspension. It is a sterile suspension containing 20% sulphathiazole in very fine crystalline form, far finer than ordinary crystals. Since sulphathiazole has a low solubility, these smaller crystals give a much better chance of the sulphathiazole getting into solution. The suspension can be applied much more effectively than powder to deep wounds. It has a pH between 5.5 and 6.5, and is said to be stable.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY OCTOBER 27 1945

DOSAGE AND EFFECTS OF CHOLINE CHLORIDE

In a recent letter to this *Journal* J. A. Barclay and co-workers[1] have suggested that the dosage of methionine and choline should be much higher than the amounts used in the therapeutic trials which have been reported in the *Journal*[2] and elsewhere. They calculate that the curative dose in man would be 20 grammes of choline a day for two or three weeks, or 20 to 60 grammes of methionine a day for a period as yet undetermined. For the moment such quantities of methionine can be dismissed as unobtainable for general therapeutic use. Choline is a simpler and cheaper compound, and as it is likely to be the subject of further therapeutic trials in diseases of the liver and kidneys and in protein malnutrition, the following observations on dosage and toxic effects may be of value to intending prescribers.

Twenty years ago physiologists and physicians were interested in choline chiefly because it was the parent substance of acetyl choline. It has, in fact, much the same action on the autonomic nervous system as acetyl choline, acetyl-β-methyl choline, and carbamyl choline, though it is far less potent. Sollman[3] states that cats show no ill effect after the slow intravenous injection of 15 mg. per kilogramme of body weight; 35 mg. per kg. are fatal. As the choline is rapidly destroyed, 0.8 to 0.9 mg. per kg. a minute may be injected "practically indefinitely." This corresponds to a dosage of approximately 3 grammes an hour in man. Slow intravenous injections have been recommended for the treatment of paralytic ileus, and this probably represented the only therapeutic indication for choline until the last two or three years. Both the *British Pharmaceutical Codex* (1934) and the *Extra Pharmacopoeia* (Martindale, 1941) give the dose for this purpose as 10 grains (0.6 g.) intravenously, though the latter subsequently recommends "10 g. in 180 ml. of normal saline," which is presumably a misprint.

During the past decade a considerable literature has accumulated on the nutritional significance of choline. It is now regarded as an important constituent of the vitamin B complex which is concerned in the transport of fat in the body and is essential for the health of the liver and the kidneys. As a consequence choline chloride has been used in the treatment of acute and chronic disease of the liver in man. On theoretical grounds more might be expected of choline in chronic enlargement of the liver and the fatty type of cirrhosis than in acute hepatitis or in the shrunken liver of atrophic cirrhosis. Therapeutic trials of choline in cirrhosis so far reported have been carried out without controls, and a decisive answer will not be obtained until a large number of cases is collected and alternate patients are treated with and without the drug. Reports on the treatment of isolated cases of acute hepatitis or acute necrosis are likewise suspect. It is difficult to follow Barclay's argument that results become more convincing when they are buttressed by metabolic data; changes in metabolism are just as much subject to the statistical law of variation, and demand just as careful controls, as clinical improvement or deterioration. Our purpose, however, is not to assess the clinical value of choline but to discuss the dosage by mouth and the possibility of toxic effects from long-continued administration.

The daily requirement of choline chloride has been estimated approximately in the growing rat. Griffith[4] puts it at 4 to 6 mg., and Engel[5] at 10 mg. for a 40-gramme rat. This works out at 250 mg. per kilogramme of body weight. This figure probably represents the order of dosage required in man, for, although the growing rat has a high rate of metabolism and therefore uses a lot of choline compared with an adult man, this is balanced by the fact that the dosage of vitamins in disease has to be much higher than the maintenance dose. In the dog, Fouts[6] has used 100 mg. per kg. of body weight to counteract the effects of a low protein diet, but Kaplan and Chaikoff[7] found a higher dose necessary to exert a curative action on the fatty liver of experimental animals. They had to give 400 mg. of choline chloride per kg. for more than three weeks to reduce the fat content of the liver of the depancreatized dog to normal levels. Dosage in man has hitherto been a good deal lower. Broun and Muether[8] treated four patients with cirrhosis with choline chloride in a dosage of 1 g. daily for periods up to two years. Russakoff and Blumberg[9] in ten cases of cirrhosis gave up to 6 g. of choline chloride a day in divided dosage. One of their patients, who was given 0.5 g. of choline chloride on an empty stomach, complained of nausea, which was associated with a slight drop of blood pressure and slowing of the heart; otherwise there were no ill effects. Their highest single dose appears to have been 1.5 g. Richardson[10] gave 1.5 g. of choline chloride a day for eight days to sixteen patients with infective hepatitis without appreciable effect.

Only one author has described ill effects from continued administration of choline chloride, and his observations have not been confirmed in man. Davis[11] has reported that the red cell count in dogs falls when they are given choline chloride by mouth for fifteen days or longer. He observed a fall when the choline was given in a single dose of 8 mg. per kg. a day, but the effect was greater when 10 mg. per kg. of choline chloride was given thrice daily.[12] The anaemia was attributed to dilatation of the blood vessels by the choline and increased supply of oxygen to the bone-marrow. Davis suggested the possibility that dogs prepared in this way might be used for the biological assay of liver extracts for the treatment of pernicious anaemia.

Davis[13] has also reported that choline chloride in a daily dose of 100 mg. by stomach tube is effective in partially reducing cobalt polycythaemia in rabbits. These experiments have not been supported by observations on man. Cartwright and Wintrobe[14] found that choline chloride had no effect on the blood count in man when given in doses of 10 mg. per kg. of body weight orally three times daily, and choline chloride has been tried without success in a smaller dosage in polycythaemia in man.[15] [16] Finally, there is the paradox that Moosnick, Schleicher, and Peterson[17] report the cure of a refractory case of pernicious anaemia by means of intravenous injections of choline chloride, 1 g. daily. They suggest that fatty infiltration of the liver prevented successful elaboration of the liver extract and that the infiltration was removed by the choline.

The conclusion from the literature is that the effective dose of choline chloride for the treatment of disease of the liver or kidneys, and for disturbances of nutrition or metabolism, is likely to be at least 100 mg. per kg. of body weight, or 6 g. a day in an adult man, and it might be three or four times as high. In other words, the curative dose of choline chloride must approach close to the toxic dose. The danger is a sudden flooding of the circulation with choline and consequent depression of the heart and blood-pressure. This has happened with as little as 0.5 g. taken on the fasting stomach in man. This danger and other disadvantages may be circumvented by intravenous drip therapy, as Barclay suggests, but whatever expedient is used treatment with choline will need careful supervision if it is to be both effective and safe. The risk of depression of the bone-marrow can probably be discounted, but it would be well to keep a watchful eye on the blood count until more is known about the reaction of the human marrow to high dosage. Furthermore, we cannot regard the therapeutic failure of choline in human polycythaemia as completely demonstrated until maximum tolerated doses have been tried.

LUNG DISEASE IN COAL-MINERS

To do justice to the fascinating material in the third report recently issued by the Medical Research Council's Committee on Industrial Pulmonary Disease[18] would tax the ingenuity of the most experienced abstracter. In a small volume of 94 pages is accumulated what must surely be a unique series of experimental attacks on the fundamental problems of coal-miner's disease, carried out quietly and with restraint at a period when the world's greatest war was being waged. It will be recalled that the committee's scheme of inquiry included a medical survey and related pathological studies of chronic pulmonary disease in South Wales in terms of the environmental background. Previous reports have dealt with these facets, ranging over physical, chemical, and petrological no less than medical peculiarities. The third report is a complementary one, and describes the experimental problems which have been encountered. It must be a source of satisfaction to the committee that a convincing answer to many queries has been given by their colleagues in the laboratory.

Before attempting to give some idea of what awaits the reader it will be useful to remind him of the trend of previous investigations sponsored by the committee. A careful survey established beyond doubt the responsibility of air-borne dust as a factor of first importance in the production of coal-miner's disease. Chemical and petrological investigations of the nature of such dust, and of the coal seams and adjacent rock strata from which the dust is derived, brought out the complexities of the disease-producing agent, and suggested that variations in the incidence of pneumoconiosis might depend on differences in the dusts. It can now be stated that the composition of mineral residue obtained from the lungs varies with the occupation of the miners, according to differences in the dust-producing strata in which the men work. Although anthracite colliers show no significant increase in dust or total silica or quartz with increasing degrees of fibrosis of their lungs, the group as a whole has an increased quartz residue when the picture of silicotic nodulation is impressed on the pulmonary tissue. Prof. E. J. King and his co-workers consider that quartz, rather than mica or kaolin, constitutes the chief hazard, though its activity may be modified by the other dust components. Some idea of the relative importance of the various dusts as agents of disease may be obtained by introducing them into the lungs of experimental animals—a method developed by the late Prof. E. H. Kettle. Belt and King find that the purest coal dust, whether anthracite or steam coal or bituminous, has a low pathogenicity. Animals so treated show little fibrosis in their lungs even after the lapse of long periods of time. As the content of siliceous material in the coal dust increases so do its pathogenic properties. Mixing quartz dust with shale dust, which is lowly pathogenic, substantially reduces the harmful nature of the quartz. Mixtures of quartz dust and coal give a confluent fibrosis more closely allied to that seen in coal-workers than the lesion resulting from pure quartz dust. It is apparent that many factors are concerned in the production of the South Wales pulmonary disease; among them are the quantity of siliceous matter in the inhaled dust and the presence of mineral matter which modifies the deleterious action of silica. The problem is complicated by the observation that some siliceous dusts are harmful and others relatively harmless; so far there is no clear explanation for these differences. In accounting for the injurious effect of silica the possibility of a toxic action on tissue cells when it is in solution has to be considered. The difficulties encountered in establishing this hypothesis are set out in the admirable report of Prof. King, who has earned the gratitude of at least one reader for the lucidity he has brought to a forbidding chemical labyrinth. In general it seems to be true that the more soluble a siliceous dust the greater its toxicity; but there are many exceptions to this generalization, and further investigation is required for a satisfactory answer.

What, then, is the present position of the coal-miner's problem? The third report of the Medical Research Council's committee suggests that quartz is probably the most noxious factor, but that its action is modified by admixture with other substances. The South Wales dust is composed of small amounts of quartz mixed with large amounts of coal and other minerals, either of which may contribute its part or even exert an antidotal effect on the action of the quartz. This sort of explanation might account for the decrease in incidence of pneumoconiosis among colliers in South Wales with the rank of the coal mined, from high in anthracite to low in bituminous coal. In other words, there must be considered a number of possibilities, such as a generally higher dust concentration in anthracite mines, differences of interaction of quartz with different types of coal, or differences of modification of quartz effect because of varying mineral composition of the shales and other strata associated with the coal. It seems likely at the moment that all these factors are involved in causing the differences in the incidence of pneumoconiosis—a truly formidable prospect for the investigator. If the M.R.C. reports are an indication of the energy and inspiration which will be directed in the future towards a most difficult problem, there need be no room for pessimism over its solution.

THE EFFECTS OF LIGHTNING

Since Seneca, doctors and philosophers have for centuries been interested in the diverse and often bizarre sequelae of lightning-stroke, and the manner of death. Pliny's opinion that a person who has heard the clap of thunder and seen the lightning flash can consider himself safe from that particular hazard has a curious topical ring in view of the beliefs as to survival during aerial bombing and falling V1 and V2 projectiles. Among the seventeenth- and eighteenth-century writers on fulguration we can with benefit re-read J. A. Dietericus,[1] J. A. Münnich,[2] F. J. Baier,[3] C. F. Hoffmann,[4] and J. G. Biedermann.[5] In the nineteenth century more serious attempts were made to study the physiology and pathology of lightning-stroke, and the monographs by Bonnet[6] and by F. Sestier[7] are classics. L. Weber's report on the Schleswig-Holstein disaster of 1878, in which 92 people were struck and 10 killed, may be taken in conjunction with F. Panse's account[8] of the Königstein incident, where, out of a party of 29, 3 were killed and 26 temporarily paralysed. Charcot was particularly interested in the neurological effects of lightning—a phenomenon which he termed "keraunoparalysis." In more recent years the subject has been written up by H. A. Spencer[9] and by M. Critchley.[10] [11]

The Goulstonian Lectures of Dr. A. J. Jex-Blake on "Death from Electric Currents and by Lightning"[12] are well remembered. This same author has lately contributed a paper to the *East African Medical Journal*[13] dealing with modern ideas on the physics of lightning. We learn that the electrical potential between the two ends of a flash is around a thousand million volts. The current is direct, amounting to 20,000 amperes at least, and the quantity of electricity conveyed averages 20 coulombs. Most of the energy is converted into heat, but there also appear Hertzian waves (or "atmospherics") with a frequency of 20,000 or so. According to Simpson's "breaking-drop" theory[14] it is considered that electricity separates whenever a raindrop breaks up into a number of smaller particles. The water becomes positively charged, the air negatively. The upward movement of warmed air brings about an electrical separation. A single flash occupies a thousandth of a second, and photographs demonstrate that it follows a meandering course with lateral branches, and has not the conventional zigzag shape depicted by artists. When lightning strikes sandy soil it may produce by fusion an irregular fulgurite or lightning-stone, reminiscent of the vitreous changes brought about in Hiroshima by the detonation of the atomic bomb.

The same issue of the *East African Medical Journal*[15] contains an editorial on "What to do in a Thunderstorm." One should remain indoors, with doors and windows shut, and away from the fireplace. Telephones may be used with impunity, but the neighbourhood of the main electrical switch and meter should be avoided. The lead-in wire from the aerial to the wireless set should be fitted with a switch to permit earthing. Out of doors one should shun crowds, flocks of cattle, isolated trees, hedges, walls, and river banks. It is better for one's clothes to be soaking wet than dry. To hold up an open umbrella is unwise. The treatment for apparent death after lightning-stroke is prompt artificial respiration, continued if necessary for hours or until the body cools or rigor mortis ensues.

It is common knowledge that Great Britain is relatively immune from severe thunderstorms as compared with Kenya and South Africa. Nevertheless during the 29 years 1852–80 there were 546 fatal cases of lightning-stroke in England and Wales, and in the decade 1901–10 there were 124 deaths. A. G. S. Mahomed[16] considered from an analysis of 237 fatalities that lightning storms in England and Wales are commonest on the plains and oolitic uplands, but the usual belief that lightning is more frequent along the course of rivers was not supported.

NUTRITIONAL SURVEYS IN ITALY

An U.N.R.R.A. medical programme in Italy was described at a recent Press conference in London by Dr. J. Metcoff, one of two young Harvard doctors, the other being Dr. A. McQueeney, who have been carrying out nutritional surveys in that country. Dr. Metcoff explained that the U.N.R.R.A. programme had three main objectives: (1) to determine the degree of malnutrition in Italy as evidenced by clinical examination; (2) to use the results for the purpose of providing foodstuffs to meet specific needs; and (3) to bring Italian organization to a stage at which it would be able to assume responsibility. During a period of six or seven months, beginning in January last, some 34 surveys had been carried out in areas of Rome and Milan, also south of Rome, and to the north from Pisa to Ravenna. Data were obtained on the heights and weights of selected poorer children who were likely to be undernourished. The statistics were thus heavily weighted in favour of reflecting the lower levels of malnutrition in Italy, not the average nutrition. The object was to gain information rapidly, and to utilize it rather than to obtain the exact statistics desirable in an ordinary research project.

Out of some 2,500 children, about 31% showed some form of classical nutritional deficiency, and of that deficient class roughly 90% had rickets. Only 17 cases of gross inanition or profound malnutrition of the starvation type were discovered, and these were all in infants in institutions. Of the mothers examined 3.5% had classical nutritional deficiencies. Attention had been mainly directed to expectant and nursing mothers, the groups most likely to show the first evidences of malnutrition. A number of the persons examined were in refugee camps. The deficiencies most frequently suggested were in riboflavin and vitamin A.

A technical committee on nutrition had been set up by the Italian Government. Its members included eminent medical specialists, and it had issued a pamphlet as a basis for examination of the population generally, but more specifically of mothers and children. This pamphlet had been sent to about 20,000 doctors in Italy, accompanied by a record card for setting out the findings of their own examinations. The information thus gathered from the whole country was sent to the central committee, and in essence it provided a system, which was still in its early stages, for the notification of malnutrition. Dr. Metcoff believed that Italy was one of the few countries, if not the only country, which had made malnutrition a notifiable disease. The pamphlet also gave a basic food schedule for infants—a standard method which went as far as it was possible at the moment to go in this direction. Mothers and children in need would thus be enabled to obtain supplementary foodstuffs from U.N.R.R.A., the amount and kind being determined on an economic and medical basis. The economic need must be considered independently of the medical need, because it was conceivable in such a country that a person might exhibit no signs of gross malnutrition and yet be in great need of food.

The Nutrition Committee of the Italian Government, said Dr. Metcoff, had also started a series of training courses for Italian doctors. The courses were to be carried out at five universities, and the programme in the University of Rome had already begun. Each course lasted for about two weeks and consisted of some 38 hours of didactic lectures and a similar amount of time in practical demonstrations. Doctors who had been out of contact with recent developments, especially on the nutritional side and in paediatrics and maternal welfare, would thus have an opportunity of being refreshed. Infant mortality in Italy had always been high. It was difficult to determine the actual mortality at the moment, but the general feeling was that it had not been greatly aggravated. Rickets had undergone a sudden increase during the war, but no exact comparison with pre-war figures was available. There was also an increase in tuberculosis. In view of the many other causes operating in wartime favouring tuberculosis, such as overcrowding and the distribution of infected people among the population, this must not be regarded as attributable to malnutrition. Children's clinics in Italy, while architecturally satisfactory, appeared to be under-used. Some of the larger clinics were found to be caring only perhaps for two dozen children, whereas similar clinics in other countries would be serving in the course of the year a couple of thousand. Steps were now being taken for the clinics to be more adequately used.

RELAXIN

In 1854 Duncan[1] published his observations on "The Behaviour of the Pelvic Articulations in the Mechanism of Parturition." Ever since it has been recognized that a relaxation of the pelvic ligaments occurs during pregnancy, but only in the last two decades has the mystery of this mechanism begun to clear. In the 'twenties Hisaw and his colleagues[2-5] demonstrated the nature of the relaxation as it occurs in guinea-pigs, and found in the serum of pregnant animals of many kinds a substance which they called "relaxin." They prepared a powerful extract of the hormone from the corpora lutea of sows,[6] and claimed that it was distinct from both oestrone and progesterone. Confirmatory evidence was published by Brouha,[7-9] Pommerenke,[10] and Abramson *et al.*,[11] but the discovery by de Fremery *et al.*,[12] Courrier,[13] Tapfer and Taslhofer,[14] and Haterius and Fugo[15] that relaxation can be brought about by oestrogens and progesterone naturally cast doubts upon the existence of relaxin as a separate hormone. That oestrogens are capable of producing relaxation is, indeed, a fact of veterinary importance, for the consequent alteration in the morphology of the hind-quarters of cows is a cause of the fractures which occur when stilboestrol is used with a view to increasing the production of milk.[16]

These doubts have stimulated Hisaw and his colleagues to further research. They have now shown[17] that a preparation of relaxin can be made which has no oestrogenic effect in a dose 120 times and no progestational effect in a dose 500 times that required to relax the pelvic ligaments of guinea-pigs. They showed also that relaxin not only fails to bring on the physiological effects of oestradiol and progesterone but differs from them chemically in being insoluble in fat solvents. The relaxing effect of relaxin is maximal 6 hours after injection, that of progesterone 72 to 96 hours later. The injection of progesterone into intact animals (but not into those which have been castrated and hysterectomized) is followed after the same interval by the appearance of relaxin in the blood. Progesterone, moreover, cannot bring about relaxation in castrated and hysterectomized animals. It seems probable, therefore, that the relaxation it causes in intact animals is due to the fact that *it stimulates the formation of relaxin in the genital tract.* Oestradiol is likewise capable of doing this in intact animals, and in castrates, but not in castrated hysterectomized females. In them, however, it potentiates the action of injected relaxin, and it has in all probability some independent relaxing activity. It is noteworthy that so far relaxin has been found only in conditions in which progesterone is normally present. One of the functions of progesterone may well be the formation of relaxin in the uterus. In unpregnant females only the concentration found in pseudo-pregnant animals can be experimentally achieved. This is one-fiftieth the concentration found in normal pregnancy, and it therefore seems likely that the placenta is the main site of formation of relaxin.

Although the changes induced by relaxin in animals are not identical with those found in women, they are similar enough to suggest that a parallel mechanism is at work. Moreover, relaxin has been found in the serum of pregnant women by Abramson and his colleagues.[11] The possible clinical significance of these findings is obvious, and further work on the human subject will be eagerly awaited.

The Minister of Health (Mr. Aneurin Bevan) is reported to have stated at a meeting of the Society of Physiotherapists on Oct. 20 that by the early months of 1946 he would be presenting a Bill in the House of Commons for a comprehensive health service.

ANNUAL HARVEIAN COMMEMORATION

THE PRIME MINISTER WITH THE ROYAL COLLEGE OF PHYSICIANS

The Harveian Dinner of the Royal College of Physicians was held at the Dorchester Hotel on St. Luke's Day, when Lord Moran presided over a company numbering about two hundred. The principal guests were the Archbishop of Canterbury, the Lord Chancellor, the Prime Minister and several members of his Cabinet, the Prime Minister of Canada, Mr. Anthony Eden and other members of the late Government, the French, Soviet, and Chinese Ambassadors, the Lord Mayor of London, the President of the Royal College of Surgeons, and representatives of other medical bodies, including the President and the Chairman of Council of the British Medical Association. It was a notable occasion, and not least because of the blend of seriousness, wit, and brilliance as represented in the speeches of the Prime Minister, the Archbishop of Canterbury, and the President of the College.

The **Prime Minister**, who said that though he spoke as a layman he could claim many doctors in his family tree, both as ancestors and as collaterals, proposed the health of the Royal College. Since the foundation of the College, over four hundred years ago, it had played a noteworthy part in contributing to the health and happiness of mankind, and it was well in these days of change, when so many monuments of the past were being swept away, to consider the continuity of effort directed to a single aim which the College represented.

Mr. Attlee went on to speak of two outstanding advances in medicine during the war, one of them, which would have been of special interest to Harvey himself, the development of the blood transfusion service, and the other the discovery of penicillin. But in mentioning these advances on the research side he wished also to pay tribute to the personnel of the medical profession, both in the fighting Forces and in civil practice. Here he digressed to speak of the services rendered by the President to the late Prime Minister:

> "We in the War Cabinet often had great anxiety owing to the vigorous travelling habits of our wartime Prime Minister, and it was always a comfort to know that on these expeditions he was under the care of Lord Moran."

After saying that he could give no details of the Government's proposals for a National Health Service, Mr. Attlee proceeded:

> "We seek a service which will be comprehensive in the double sense of being available to every member of the population and of covering every form of medical and allied activity. We intend to have a service in which no patient shall be without the treatment he needs through lack of money or through deficiency in or lack of organization of the necessary facilities. We need, too, a service in which professional men and women will be able to devote themselves to their great calling without financial anxiety and without in any way feeling cramped and over-controlled by regulations."

He spoke of the need for a great improvement in the hospital service, in the facilities for diagnosis and treatment outside hospitals, in the number and distribution of medical men, both consultants and general practitioners, and perhaps above all in the planning and organization of all the different branches into a single integrated service. "The task is not easy, but we are going to do it. Above all we realize—no one more keenly than my friend the Minister of Health, who is here this evening—that for this to be successful we must have the help and co-operation of the profession itself."

Doctors and Politicians

Lord **Moran** began by giving a little ancient College history. In 1637, when the College prepared for the Government a report on the health of the people—a report which would do credit to any modern medical officer of health—it ended by proposing a Ministry of Health. The actual words were: "They suggest the provision of a commission or office of health, which has been found useful in Spain, Italy, and elsewhere." The Ministry was established nearly 300 years later. The College still made suggestions, and on the whole he thought the tempo had quickened a little! Truth compelled him to say that not all the College pronouncements were so prescient. In 1648 it pronounced public baths hurtful to the commonwealth and cited the experience of Athens and Rome to show that they caused physical effeminacy and debauchery of manners.

Politics and medicine, Lord Moran went on, had certain things in common. The Prime Minister of one of the Dominions once said to him that the great thing in politics was to avoid mistakes, and certainly in the practice of medicine the best physician was the one who committed the fewest errors in diagnosis. How was this done? The physician who never for a moment forgot the distinction between what he knew and what he only thought he knew would not go far wrong. But if as he grew older and vainer he refused to admit that he was fallible, his mistakes would multiply. A physician who in the hubbub of success had lost his humility was not a safe guide.

A kind of success could be won in both professions by the "gift of the gab." He supposed that the greatest danger to the doctor's integrity of mind was the credulity of his patients. A friend of his, one of the ablest Ministers in the last Cabinet, once confided to him that at all times and in every ill he had found salvation in the manipulations of a certain gentleman, "I forget now whether he twisted his neck or merely pulled his leg." Was the quality of credulity entirely lacking from the audiences which hung on the words of politicians in Parliament and in the country? Was it not true that in a democracy the gift of public speech had an undue advantage over other qualities? And if the credulity of the public was a snare to both professions, what was the remedy? It could only be the education of public opinion.

> "Will medicine and politics go forward into the future in step? I wonder. Medicine is becoming more scientific. The glittering victories she has won in the field of bacterial disease by the discovery of penicillin and by the use of sulphonamides have enriched our resources. The physician of to-day is twice as well equipped in the war against disease as he was when I was a student. The physician who knows what is wrong with a patient and has an effective remedy in his hands can 'cut the cackle.' He has no need of it. The doctor's patter has been the subject of ridicule from Molière to Bernard Shaw, but the profession has been weaned from this patter because it has been armed. The task of the politician is less simple. Even more than the doctor he has to deal with the vapours in man's mind. . . . But let me end my comparison of politics and medicine with this admission, that while medicine has riveted the attention and absorbed the energies of some of the ablest of our race, the government of man, which is the business of politics, is the greatest of all human studies."

Responding to the toast of the guests, proposed in a speech of commendable brevity by Dr. John Parkinson, Harveian Orator, the **Archbishop of Canterbury**, who enlightened the occasion with a wit that delighted everyone, referred to his close connexion with the King's School at Canterbury, mentioning that he had only discovered that afternoon that two old boys of that school bore honoured names in the early history of the College. One was Thomas Linacre, founder and first President, and the other was William Harvey himself. Both of them were also Oxford men—one a Fellow of All Souls' and the other Warden of Merton, the two Colleges of which the Archbishop of Canterbury was always Visitor.

They were all thankful, the Archbishop went on, that medicine could now turn from salvaging the wreckage of fratricidal war to peaceful and constructive tasks. The medical profession had always been governed and disciplined by the zeal for scientific truth, the passion to serve society, and the sense of personal vocation. "Although we expect the members of the medical profession to know their job scientifically and to serve the public well and skilfully, what in the end we treasure most about them is something in their character which is the proof of their personal vocation and devotion, and we all pray that that may never grow less in this great profession."

Mr. **Ernest Bevin**, the Foreign Secretary, who also responded, said that this was not his first experience of the College. He had attended an earlier dinner in which he had ventured to ask for the help of the members of the College in industrial health and welfare, and he expressed his appreciation of the progress made in that field, although it was not so much as he would have liked. He also referred to the work done by the joint committee of the Trades Union Congress and the British Medical Association, which he thought had done a great deal to bring the medical profession nearer to men and women at their work. A tragic shortage of efficient man-power would exist in this country for several years to come. This was due to two causes—the losses of the last war, which were now being felt in the scarcity of responsible men between the ages of 45 and 55, and the losses of this war, as measured not only in life but in interruption of training. The devastation in Central Europe, the loss of productive capacity all over the world, the tremendous wealth of the United States, the enormous power of Russia, all made it evident in different ways what a great burden was laid upon the British people if British leadership was to be maintained. During the next twenty-five years they could not afford to lose a single productive unit. "I know that you as one of the great professions will cast aside any prejudices you may have, and just as you flung everything on the altar to resist the enemy, you will place your great ability to the fullest extent to the common service in order that this country may survive and still play its part in human destiny."

RHEUMATIC FEVER AND HEART DISEASE

The annual Harveian Oration founded by William Harvey in 1656 was delivered on Oct. 19 at the Royal College of Physicians of London by Dr. **John Parkinson**, physician to the cardiac department of the London Hospital and to the National Heart Hospital.

Dr. Parkinson said that Harvey, by his discovery of the circulation, confined to the blood and the blood vessels the evil humours of early writers which were regarded as the cause of rheumatism. In the 17th century rheumatism was differentiated from gout; in the 18th century rheumatism was first recognized as being associated with the heart, and in the 19th century this association was confirmed.

Rheumatic fever of childhood was the main source of heart disease up to the age of 40. The damage was done between the ages of 5 and 15, and it exceeded tuberculosis as a cause of death to the age of 20. During this war, as in the last, large numbers of our young men were found unfitted for service because of valvular disease of the heart directly due to juvenile rheumatism. It was estimated that almost one-tenth of all rejections were on account of heart disease. In peacetime the economic loss each year could be judged by the fact that the duration of economic activity in these men was no more than ten years on the average. All were agreed that poverty and overcrowding were basic causes, and rheumatic fever was rare among children of the well-to-do. Anything a Government did in these directions would reduce the incidence of rheumatic heart disease.

Dr. Parkinson said there was almost unanimous opinion that compulsory notification of rheumatic fever was essential to progress, for it would permit its early diagnosis before heart disease had taken hold. The excellent scheme for rheumatic children now in operation by the London County Council was regarded in the United States and elsewhere as the most comprehensive in existence; but doctors knew, and the public should know, that institutional treatment from the outset, and subsequent supervision, would have to be extended to every case of rheumatic fever occurring in this country. There should now be created a Rheumatic Fever Committee to co-ordinate research and plan for the future. The Orator believed that the Royal College of Physicians was prepared to take a lead in this great endeavour. The objective should include one main country hospital for research, and hospitals and clinics to serve all densely populated areas. Ultimately it would be found necessary, as it had been in the United States, to create a National Council for Rheumatic Fever and Heart Disease.

HEBERDEN SOCIETY MEETING

The Heberden Society will begin its first post-war academic year with a two-day meeting in London on Friday and Saturday, Nov. 2 and 3. This clinical and scientific society, founded in 1936 for the advancement of the study of rheumatic diseases, and closely associated with the Empire Rheumatism Council, has been so reorganized that membership is now drawn from all centres in the British Isles, notably the universities and spas. The inaugural general meeting, which is timed to coincide with part of the post-graduate course arranged by the Empire Rheumatism Council (see *Journal*, Oct. 13, p. 516), opens on Nov. 2 in the rehabilitation unit of the Royal Free Hospital at 4 p.m., when during tea there will be exhibits. A short business meeting will be followed at 4.45 p.m. by a lecture-demonstration on recent advances in physical methods by Dr. C. B. Heald in collaboration with Fl. Lieut. B. C. Elliott, Dr. Graham Weddell, and Sister F. L. Greenhill. (Medical practitioners attending will be welcomed to tea, provided they apply for a tea invitation to Miss Bereton, 91, Priory Road, West Hampstead, N.W.6.) On the same evening the members will dine at the Euston Hotel. On Nov. 3 at 10 a.m. at the Middlesex Hospital Prof. B. Windeyer will give a lecture-demonstration on the treatment of ankylosing spondylitis by *x* rays.

BRITISH CIVILIANS RELEASED IN CHINA

We have received from the War Organization of the British Red Cross Society and Order of St. John of Jerusalem a preliminary report—dated Sept. 11, 1945, Shanghai—on the British inmates of civil assembly centres. The author is Dr. W. S. Flowers, the War Organization's medical superintendent in China.

Health of the Inmates

The physical condition of the 5,570 internees in the several internment camps is surprisingly good. Despite crowded living conditions, some deficiencies in diet, and inefficient and uncertain sanitation (which in Ash Camp was found to be both primitive and inadequate), no serious epidemic diseases have broken out. There has been a good deal of malaria, particularly in Lunghwa Camp, where a very unreliable water supply could be maintained only with much labour and worry, and where 45% of the interned had one or more attacks of malaria. Yangtzepoo Camp has had a mild epidemic of amoebic dysentery, while all camps have had dysenteric diarrhoea. One camp had an epidemic of whooping-cough which affected most of the children. There have been recently a few sporadic cases of encephalitis japonica, from which the mortality among the stateless outside the camp has been as high as 75% but has not so seriously affected the internees in Allied camps. Otherwise the physical condition of the people, including the children, has been well maintained. This has been largely due to the untiring labours, vigilance, and medical nursing care provided by a fine team of doctors and nurses in each camp, and dental facilities were made possible by a good team of dentists. Equipment was limited and supplies were often short, but by improvisation and local purchases an amazing medical service was developed and maintained.

The figures under a rough-and-ready classification are as follows: Ash Camp, 424 persons; Yangtzepoo, 1,122; Pootung, 881; Lunghwa, 1,538; Chapei, 703; Lincoln Avenue, 295. Up to the present we have no report from Yangchow (total 607), but anticipate that the internees there will be in equally good health.

While the physical condition of these people is good, they are all obviously very tired, many have lost a good deal of weight, the majority are definitely anaemic, and all are eager to escape from "camp life" as early as possible. The camp mind and outlook is psychologically interesting: memory is unreliable, and outlook and interests have been narrowed. The mortality has been low—if anything lower than it would have been had these people been living the normal rushed life of civilization. The majority of deaths have been among the aged from natural causes. There has been no typhus, typhoid, or cholera.

Nutrition, Housing, and Recreation

Nutrition has varied considerably from week to week. The average level was above 1,700 calories per head. Occasionally it fell below this as a punishment for escapes or attempted escapes. Fats were not very plentiful, milk for the children was always in short supply—generally about 6 oz. could be allowed daily to them. Adults often went short to maintain the best standard possible for the young, who are uniformly in pretty good shape. Detailed charts of the nutrition show peak periods when parcels came in and low periods when punishment was meted out. Recent liberal supplies from United States sources have adequately supplemented all previous deficiencies. Vitamin extracts have generally been sufficient to make up for other shortages.

The accommodation provided allowed 40 sq. ft. per person. The barrack-like buildings which were converted into dormitories allowed of little privacy, only curtains dividing the families. For the large majority there was obviously no escape from the crowd by day or night. Most places had room for some recreation, but Jap guards prevented any wandering over the fences. They would not allow the preventive units formed to wander into the paddy fields to prevent the breeding of the mosquitoes responsible for so much malaria. Sanitation was rarely very good, and only by the labours of the internees themselves was some hygiene maintained. The kitchens where they worked in shifts for the cooking of their own food were very primitive and must have demanded incessant effort to keep clean. Water supply, except at the Lunghwa camp, was generally good.

Recreation fields were laid out where there was room by their own labours. Football and tennis were possible part of the year. Exercise was practised by all at first, but towards the end few had energy for it. Schools for the children were run in the camp by a band of teachers, and the children sat their exams. even up to matriculation. Lectures, concerts, plays, and opera filled in the evenings, and there were few signs of boredom. It all represents a refusal to be hindered by circumstances from pursuing a free and enjoyable life.

Summary

The health record is good. All are tired, many are anaemic, and many are affected to a greater or less degree by psychological changes. Conditions were favourable for large epidemics, but none developed.

Malaria could not be prevented in view of Japanese control, but was adequately treated. Morale was maintained throughout, despite the mixed community assembled together in such close proximity and lacking all privacy, by the efforts of enthusiastic leaders, teachers, and entertainers.

Reports of Societies

INTERNATIONAL BIOLOGICAL STANDARDS

DIXON MEMORIAL LECTURE BY SIR PERCIVAL HARTLEY

The Walter Ernest Dixon Memorial Lecture was delivered in the Section of Experimental Medicine and Therapeutics of the Royal Society of Medicine on Oct. 9 by Sir **Percival Hartley**, Director of Biological Standards, Medical Research Council. Dr. E. H. **Allott** presided.

After a tribute to Dixon, one of the earliest advocates of the biological standardization of drugs, Sir Percival described a biological standard in its simplest form as an arbitrarily chosen but representative sample of the substance for which it was to serve as a basis of measurement, preserved under conditions ensuring its permanence. A unit might be defined as the specific biological activity contained in a certain weight of the standard. The first biological standard to be established was for diphtheria antitoxin, the discovery of which by von Behring was announced in 1890. Then followed Ehrlich's remarkable series of researches, amongst the most famous in immunology, which laid the foundation of biological standardization as it was known to-day. The supply of standard diphtheria antitoxin from Ehrlich's institute at Frankfurt ceased with the outbreak of war in 1914, and this withdrawal rapidly led to the establishment of the standard on an international basis and to the creation and adoption of international standards for other substances.

In 1921 an international conference in London recommended the adoption of Ehrlich's original unit as the international unit, and in the following year a second international conference in Paris explored the possibility of establishing standards and units for other antitoxin and antisera. As an outcome of this and later conferences international standards for digitalis, pituitary (posterior lobe) extract, insulin, and the arsphenamines were adopted, and a Permanent Commission on Biological Standardization was set up by the Health Organization of the League of Nations to provide international standards and units and to secure their widest acceptance. Within less than twenty-five years 35 international biological standards had been established, and even during the recent war progress had not stopped, for standards for vitamin E (1941), heparin (1942), and penicillin (1944) had been adopted during that period.

International Achievement

The materials for biological standards had come from many countries, but in all but seven of them the final operations to secure conditions of permanence and stability had been carried out in England, and for all but two of these at the National Institute for Medical Research, Hampstead. Five of the original international serum standards were made at Hampstead, and a number of equivalent international standards had also been made there for the purposes of the Therapeutic Substances Act and the *British Pharmacopoeia.* To illustrate the international character of the work, the lecturer mentioned that material for the serological standards was supplied from England, Denmark, and the United States; the tuberculin standard was made in England; material for the vitamin standards came from Switzerland, Dutch East Indies, Hungary, England, France, Germany, Sweden, and the United States; that for the arsphenamines originally from Germany and the United States and later from England; the first insulin standard was made in England and the second in Canada; the material for both pituitary (posterior lobe) standards was supplied from the United States and manipulated in England; the first digitalis standard was prepared in Holland, the second in England; ouabain standard material was supplied from France; materials for the sex hormones were supplied from eight countries; Canada provided the material for the heparin standard, and the United States and this country the material for penicillin.

Practically all the material for these standards was presented to the international organization, some of these gifts representing very large sums of money. A laboratory in Switzerland presented 30 grammes of androsterone to provide the replacement standard for male hormone activity; a laboratory in England presented 20 grammes of the purest beta-carotene to provide a replacement standard for vitamin A, and another presented 30 grammes of pure crystalline penicillin sodium salt for the standardization work in Hampstead. Free distribution was made of all standards issued from Hampstead, on a national basis or to the British Commonwealth or to individual research workers anywhere, as for the international standards.

Standard for Penicillin

After recounting the course of events which led to the adoption of international standards for vitamins and the subsequent action in this field, Sir Percival Hartley turned to the latest standard, possibly the last, established by the Permanent Commission—namely, the international standard for penicillin. For many reasons, he said, it was desirable that an international standard for penicillin and an international unit defined in terms of it should be agreed and established without delay. Delegates from five countries with expert observers from certain others met in London a year ago under the chairmanship of Sir Henry Dale, and unanimously recommended the adoption of a sample of pure sodium salt of penicillin II as the international standard, and, for practical reasons which were justified at the time, a sample of a calcium salt of penicillin as the international working standard. The international unit was defined as 0.6 microgramme of the international standard, and such unit was contained in 2.7 microgrammes of the international working standard. Decisions as to nomenclature and other matters were also recorded by the conference.

At Hampstead they were now almost ready for the final stages of giving effect to these decisions by the world-wide distribution of penicillin standards. He exhibited a sample of the international standard, mentioning that at Hampstead they had over 300 such small containers, each holding about 30 milligrammes; also a sample of the international working standard, of which they had 200 containers, each containing about 65 milligrammes. The actual international standard preparations obviously could not be used for the routine assays of penicillin; there were not enough of them; but they were supplied for the assay and periodical check-up of equivalent national standards which the national control centre of each country was expected to prepare.

The Oxford Unit

The first standard for penicillin was made at Oxford, and the unit of activity, which came to be known as the Oxford unit, was defined as that which was contained in 0.23 milligramme of this preparation. In one way or another the original Oxford unit had been redetermined in many other, more active preparations. At Hampstead they were provided with two such accurately assayed preparations—one containing 71 and the other 84 units per milligramme—and with these the potency of the British standard for penicillin—155 units per milligramme—was assayed. These three preparations, with two others from the United States carrying the Oxford unit, were included in the samples examined by the London conference a year ago. The results of the assays, despite the different methods employed by the collaborating laboratories, showed remarkably good agreement. There was sound evidence that the value of the unit which was being used a year ago in the United States was the same as the value of the unit being used in this country; from which it certainly seemed that, in spite of the repeated redefinition of the unit in both countries, the original value as defined at Oxford had not been significantly varied. Finally, the value of the unit recommended for international adoption was approximately equivalent to that originally adopted at Oxford.

Impending Developments

Sir Percival then discussed the important part which international biological standards had played in ensuring the high quality of therapeutic substances. The Therapeutic Substances Act had for nearly 20 years controlled the supply of certain drugs and medicaments, but it was limited in scope and in geographical application. For example, its control did not extend to the vitamins or heart drugs, and its application was restricted to Great Britain and Northern Ireland. A way had been found, however, whereby both these limitations might be overcome—namely, by including all the substances for which international biological standards had been established in the *British Pharmacopoeia*, and the *Pharmacopoeia* on its part had laid down the principle that the standards and units to which pharmacopoeial preparations must conform were the international biological standards and units. In some parts of the British Commonwealth and Empire a control over these substances similar to our own had been established, and in these countries also international standards were in general use.

After describing the interesting replacement operations which had taken place from time to time in respect of 18 of the 35 standards, including the first insulin standard and the first standards for pituitary (posterior lobe) extract and for vitamin B_1, the lecturer said it was quite likely that a new international organization which might replace the Permanent Commission of the League of Nations would decide that standards for antisera and some of the antitoxins could be dispensed with, and that arsphenamine—the original "606"—had earned an honourable retirement. The position of vitamin standards might also come under review. As Sir Henry Dale had picturesquely put it, "The ultimate aim of biological standardization, as of all preventive medicine, may be regarded as self-extinction." But there were new candidates with good claims to admission. The standardization of the diphtheria prophylactics was a problem of outstanding importance and urgency. The establishment of an international standard for tetanus toxoid for the active immunization of man might well have an early priority. Some of the investigations carried out at Hampstead regarding the standards for and the assay of gas-gangrene antitoxins, which became urgent and important because of the immediate needs of the war, also indicated new directions in which the work of biological standards might develop.

International biological standards might find useful application in the rapidly developing field of chemotherapy. Pure substances could, as a rule, be fully described in chemical and physical terms, the doses to be administered could be expressed in weight, and biological standards and units were neither necessary nor desirable. It was otherwise, however, in the case of substances of proved biological activity and clinical usefulness of which the chemical composition was unknown, and successive batches of which possibly exhibited varying biological properties. For such substances, in the interim period pending the discovery of their chemical composition and structure, or perhaps of a more reliable process of manufacture, experience had shown the value of the adoption of a standard by comparison with which other preparations could be matched.

THE "DISCHARGING LESION" IN NEUROLOGY

At a meeting of the Neurological Section of the Royal Society of Medicine on Oct. 4 the new president, Dr. J. Purdon Martin, delivered a presidential address on the subject of the "discharging lesion" in neurology.

The theory of the "discharging lesion" was propounded by Hughlings Jackson to account for convulsive phenomena, but Dr. Martin considered that it was capable of a wider application in neurology than had hitherto been accorded to it. The theory postulated that nervous tissue (and therefore nerve cells, inclusive of their axis cylinders) "stored up" energy, and under the influence of physiological stimuli some of this energy was emitted in an orderly and controlled manner as impulses, but that under certain abnormal conditions the energy might be discharged without a physiological stimulus, and then in an excessive, uncontrolled, and disorderly fashion. A portion of nervous tissue which was in a pathological state such that it was liable to discharge in this manner constituted a "discharging lesion." Modern physiological knowledge lent much support to this theory, and he (Dr. Martin) had in fact come to it chiefly by way of the physiology of muscle.

Jackson was mostly occupied with convulsions, but there were many other phenomena which provided objective evidence of "uncontrolled" and apparently unphysiological discharges (some of which Jackson had referred to in his writings). Observation led to the belief that discharges might be of three different degrees or varieties, which, however, graded into each other. The convulsion was evidence of a massive or explosive discharge. The smaller repeated discharges which would give rise to peripheral facial spasm, or to the muscular fibrillation of amyotrophic lateral sclerosis, might be described as "spluttering," while those that caused continuous spasm of muscles such as trismus might be called "continuous." There was evidence of a still lesser degree of abnormal instability in certain conditions in which there seemed to be an excessive motor response to normal stimuli, as in some of the motor phenomena of tetany and of tetanus and of strychnine poisoning.

Jackson considered that symptoms attributable to "spontaneous" discharge were essentially paroxysmal and transient, since the portion of nervous tissue from which the "primary" discharge occurred required time to become again "overcharged." While it was true that the phenomena indicative of massive discharge were transient, those attributable to "spluttering" and "continuous" discharges might go on for a long time, and in some instances for the rest of the patient's life. Trismus and tetany were actually continuous, while peripheral facial spasm might be said to be paroxysmally continuous. In regard to all of these we must suppose that in the discharging nervous elements the store of energy on which the discharge depended was being renewed as quickly as it was expended. A similar condition of energy exchange could be maintained and demonstrated in muscle, and was known as a "steady state." The peripheral facial spasm which occurred as a sequel of Bell's palsy was associated with an imperfectly recovered nerve. The fibrillation of amyotrophic lateral sclerosis was associated with a degenerative state of the anterior horn cells.

We might apply, Dr. Martin continued, what we have deduced from observation of the motor phenomena to the interpretation of certain sensory phenomena which patients described. After a vascular lesion of the thalamus, imperfectly recovered cells of the "pain system" might constitute a discharging lesion and achieve a steady state, thus giving rise to the spontaneous pain of continuous nature that was the characteristic after-effect of such a lesion. In other cases the degree of recovery might be such that the cells did not discharge spontaneously, but their "energy substance" remained hyperexcitable (e.g., in consequence of anoxia) so that they reacted excessively to normal stimuli. The alternative theory—that the "thalamic syndrome" resulted from a release of the thalamus from a control normally exerted over it by the cerebral cortex—was not in keeping with some of the essential facts.

In the case of a recovering sensory nerve (as in that of the recovering facial nerve) there might be a state of instability of the energy substance, and this might be the basis of that hyperalgesia which Head attributed to "protopathic sensation."

Lightning pains in tabes were attributed to discharges occurring in degenerating afferent elements. If a discharge arose in the afferent portion of a reflex arc it might give rise to reflex movements. All the organs liable to be affected by visceral crises were reflexly controlled, and such a crisis might be due to "spluttering" discharges in the afferent part of the arc, producing the effect of an irritant or foreign body in the viscus concerned.

All these symptoms had something in common—namely, an excessive, "explosive," or compelling quality. The motor phenomena referred to had also this in common—that they might occur or continue during sleep. This applied to convulsions, facial spasm, tetanus, and tetany—whereas most abnormal movements, such as those of paralysis agitans, chorea, and spasmodic torticollis, ceased during sleep. This difference might not be fundamental, because chorea had many of the features of a symptom due to "spontaneous" discharges.

The theory provided explanations for, and enabled one to see a certain unity in a number of symptoms for which the current explanations were unsatisfactory. Dr. Martin recalled a quotation from Pasteur: ". . . the characteristic of a true theory is its fruitfulness."

Correspondence

Telling the Patient

SIR,—Major J. C. Hogarth's letter on this subject (Oct. 13, p. 513) is timely and deserves more than a passing comment. Observations of the same kind have been made to me by a number of thoughtful Service medical officers—usually with unit experience—who have been frankly shocked by the impersonal methods which prevail in many Service and E.M.S. hospitals. I had frequent occasion to make similar criticisms, during the first three years of the war, as the result of my numerous contacts with E.M.S. and teaching hospital medicine.

How have these strange habits of thought and action, this routine of intensive and often repeated investigation and multiple specialist opinions, but with so little said and done for the patient *as a person*, come to characterize hospital practice ? What is the function of the physician, what is the object of medicine if it is not to help the patient's mind and body in every way possible and at every stage of his illness ? There can be no greater disservice than to leave him puzzled or in the dark. It is a sad reflection on the trends of our clinical teaching in recent decades that institutional medicine should now so frequently be allowed to degenerate into a kind of mechanical bedside pathology ; that it should prefer reports and labels to human histories, and diagnoses and treatments to "treatment," and delight so selectively in what is called the "interesting" case. "Examination, explanation, and reassurance" should be as much in the mind of the student and young doctor as "inspection, palpation, percussion, and auscultation," if—that is to say—he cannot be human without a mnemonic.

In another letter in the same issue Wing Cmdr. Bergin comments on some of the consequences of the modern "passed to you, please" ritual of investigating and handling patients. What a travesty of our old clinical discipline it is to employ a succession of specialists to exclude organic disease and then to ask a psychiatrist to make the final diagnosis, and, too often, to confirm the invalidism. The technological age in medicine has added much to our investigatory powers and has done much for many patients, but it is time our science and humanism resumed a more equal co-partnership. Two books have recently been sent to me from the United States, where similar trends are, I gather, all too common. One is called *The Patient as a Person* (by G. Canby Robinson); the other *Patients Have Families* (by Henry B. Richardson). We stand on the threshold of large reforms in our teaching and our practice. May we hope that the teachers of the new generation will take every occasion to remind their students and house-officers that "patients" are, above all, "persons" and not just "cases," and also that they have families and that they get better more quickly or accept their adversities better if they and their families are simply and clearly told what they most need to know ?—I am, etc.,

Oxford. JOHN A. RYLE.

SIR,—How cordially I agree with Major Hogarth's suggestion that the patient be given constructive information about his complaint. I would go further, and suggest that therapy is incomplete until the disease is evaluated to him in terms commensurate with his intelligence, education, and emotional maturity, and until he is helped to adjust to it.

One of my first lessons in psychotherapy—from Dr. T. A. Ross ; I have never forgotten his advice—was that the patient should be completely overhauled physically and the nature of his physical complaints precisely delimited and evaluated to him. How much more important, surely, where the complaint is predominantly physical ; or in the extending field of the psychosomatic complaint—i.e., the physical symptom due to emotional stress.

Hypochondriasis is due to—or at any rate encouraged by—ignorance or fractional knowledge. It is surely the function of the doctor—specialist or G.P.—to dispel that ignorance. In doing so he will tend to clarify his own clinical conceptions and amplify his own therapeutic influence ; by failing to do so he may become the creator of suffering. In doing so he will also help dispel the suspicion—explicit in many intelligent laymen and implicit in many more of their less articulate brothers—that much of the doctor's business is a defensive jiggery-pokery of false magic.

The doctor who has not the patient's full trust is crippling his own therapeutic influence. That trust can be more easily gained if a more rightful conception of the doctor's business is encouraged: that his influence is based, not on symbols, prestige-attitudes, or an implicit claim to a higher esoteric level of understanding, but on compassion fused with skill and experience and the ability to help the patient to see his complaints in their proper perspective.

Much avoidable psychotherapy, suffering, and distrust of the medical profession could be prevented if more doctors—specialist or G.P.—were to spend the few moments necessary to complete their therapeutic effort by bringing the patient "into the picture." It would also help those of us who come after to get a reasonable medical history. I am continually being surprised by the number of intelligent young officers who have vague ideas about quite serious illnesses and who are naturally worried because no one has told them what to expect or what to do about it.—I am, etc.,

Witley, Surrey. H. HARRIS, Major, R.A.M.C.

SIR,—Major J. C. Hogarth (Oct. 13, p. 513) surely realizes that in the out-patient department of a hospital the patients are referred for an opinion by the general practitioner. The majority of these practitioners, I am sure from personal experience, would resent the out-patient physician discussing in detail the diagnosis, prognosis, and treatment with the patient. This is the function of the general practitioner, and it is the physician's duty, in my opinion, to communicate only with the doctor concerned. Only in exceptional cases and at the doctor's request should the physician discuss the diagnosis with the patient. Otherwise, surely, essential trust and harmony between patient and general practitioner are apt to be jeopardized.—I am, etc.,

Northwood, Middlesex. E. IDRIS JONES.

Rehabilitation of Fractured Limbs

SIR,—The letters of Dr. R. Murray Barrow (Sept. 8, p. 332) and Dr. Vaughan Pendred (Oct. 6, p. 475) prompt me to point out that in 1899, when a student at Edinburgh University, I demonstrated to Prof. Annandale and Mr. J. W. Dowden at Edinburgh Royal Infirmary an electrical method of producing controlled contractions and relaxations of any of the muscles of the body. With their assistance I treated various types of fractures, particularly Colles's fractures, the latter being put in plaster and the case split in four to eight days ; then daily contractions of the extensor and flexor muscles were produced by the apparatus described, so as to cause movements of the wrist and fingers. I showed that contractions and relaxations were so finely controlled that only the slightest movements of the muscles were discernible at first, and gradually increased to the maximum required without pain until the wrist and fingers were put through their full range of movements. About the year 1905, when I was in charge of the *X*-ray Department of Great Ormond Street Children's Hospital (which I started as a department), I showed the same method to Sir Arbuthnot Lane and Mr. Stansfield Collier, who were so impressed with the results that they sent many of their fractures to me for treatment by this method. In spite of the recent literature advocating long periods in plaster I have continued to carry out this method with consistent success, and full functional use of the wrist is obtained in much shorter time than when treated by the present-day so-called orthodox method.

By the method I advocate, which has stood the test for so many years, an important factor is that the muscles can be made to contract and relax painlessly *without their point of origin being approximated*, so that considerable movement of muscles in the initial stage of treatment can be carried out without moving the fractured ends of the bone in the slightest degree. This reproduction of the function of the muscles in the neighbourhood of a fractured bone by graduated contractions acts beneficially in the following manner: (1) The contractions and relaxations gradually increase the local blood supply and aid its circulation, so that absorption of lymph and extravasated blood in the tissues is rapidly promoted and the growth of callous powerfully stimulated. (2) Slight movement at the broken ends may increase the production of granulation tissue by causing hyperaemia. (3) The movement of the muscles prevents contiguous muscles, tendons, and other structures from becoming adherent. (4) The reproduction of the physiological action of the muscle prevents their becoming atrophied. (5) By the muscle movements increasing the local blood supply, the resting bone is less likely to become atrophied. (6) By preventing adhesions and wasting of muscles, as soon as the repair of the bone is sufficiently advanced, the patient is able to regain full function in the limbs very much sooner than is possible where adhesions and wasting of the muscles result from enforced complete rest.

I can claim for this method that, if properly carried out, there is no danger and that the results in time and restoration of function are most satisfactory.—I am, etc.,

London, W.1. MORTON SMART.

Sciatic "Neuritis

SIR,—Dr. J. MacDonald Holmes and Mr. B. R. Sworn's article on sciatic neuritis (Sept. 15, p. 350) will be of great interest to all who have to try to deal with the problem of sciatic pain. But I still think that an injured intervertebral disk might account for their cases, both of which gave a history of associated trauma, for what that is worth. It is possible to envisage injury to the attachment of part of the annulus fibrosus, allowing a local bulging of the disk in the standing position which would be absent in the position at operation, and where no softening or break in the posterior contour of the annulus would be felt. I am uncomfortably aware that this explanation is highly suppositive. But I feel we should be unwilling to abandon a pathological concept which has shed so much light on sciatic pain, unless logic truly demands it.

Symptomatic relief from decompression is understandable with any pathology. But if the disk is damaged, further protrusion in the years to come might be expected. It will be interesting to know if either symptoms recur as the protrusion again fills up the extra space provided, or a demonstrable narrowing of the disk space occurs.—I am, etc.,

C. W. M. WHITTY,
Major, R.A.M.C.

Psychiatry in the Services

SIR.—As a practising psychiatrist it is with much regret that I find myself in agreement with most of the statements in Wing Cmdr. K. G. Bergin's letter (Oct. 13, p. 508); for, having myself served as a unit medical officer, I realize that there is no lack of confirmatory evidence regarding the facts mentioned. I have no doubt that the majority of unit medical officers could cite an infinite number of similar cases, and I am sure that many other correspondents will be only too glad to recall their own experiences. Personally, however, I am much more concerned in striking at the root of the trouble, and, though willing to admit that there are many first-class psychiatrists serving in the Forces, I do not agree with Wing Cmdr. Bergin's statement that the psychiatric branch can be exonerated from all blame in the matter of the treatment and disposal of such cases. It must be admitted that, owing to the shortage of trained psychiatrists, it was inevitable that the original selection of personnel for this branch was a matter of great difficulty, and, for the same reason, it was impossible to give these officers an adequate military training. It is, indeed, a well-known fact that, especially in the early part of the war, many "specialists" were appointed though there was scant evidence that they possessed more than a superficial knowledge of their "specialty."

In my opinion many of the difficulties confronting even the expert neuropsychiatrist would have been obviated if these specialists had been posted for an adequate period as ordinary unit medical officers. They would then realize to the full the actual conditions under which Service personnel—especially N.C.O.s and other ranks—live and work. This, I believe, is the crux of the whole problem, and raises a matter which is of vital importance to the future of psychiatry. Although he is obviously viewing the matter from an entirely different aspect, I think that Wing Cmdr. Bergin sums up the situation very concisely in the clause: ". . . a system which lays too much stress on psychological illness and not enough on a man's responsibility to his fellows." It is obvious that he did not intend this to be an indictment against psychiatry, but we who profess to be psychiatrists would do well to ponder and give the matter much consideration. In the past too much stress has been laid on the academic and scientific aspects of psychological medicine, and the sociological implications have not received the attention they deserve. This broader view can be achieved only when psychiatry is accepted as an integral part of the social service of the community and not segregated as a little-understood and narrow specialty.—I am, etc.,

St. James Mental Hospital,
Milton, Portsmouth.
W. LIDDELL MILLIGAN.

SIR,—Wing Cmdr. K. G. Bergin's experience (Oct. 13, p. 508) differs entirely from that of all serious writers on the subject of Service neurotics in two respects—their progress after invaliding and their response to disciplinary measures. Careful follow-ups on patients who had been invalided out of the Services for neurosis were done by Lewis (*Lancet*, 1943, 1, 167) and Ferguson (*Health and Industrial Efficiency*, H.M.S.O., 1943), it being found that the great majority were still seriously incapacitated after months of civilian life. I have encountered many patients of this type who had been harshly dealt with by the executive because of their failure to meet the demands made upon them or their supposedly malingering propensities. In each case the results were disastrous, and a completely useless individual, often with a very great nuisance value, was produced. Such eminent psychiatrists as Ebaugh (*Manual of Military Psychiatry*, W. B. Saunders, Philadelphia, 1944) on the other side of the Atlantic and Hadfield (*British Medical Journal*, 1942, 1, 281) on this have emphasized the unfortunate consequences of treating these patients as malingerers. Neurotic symptoms are very real, and the man or woman in a state of pathological anxiety and depression finds it more difficult to lead a normal active life than does a healthy person. A refusal to recognize this produces a strong sense of injustice and grievance and has a most harmful influence.

That the object of neurotic behaviour is to procure discharge from the Service is a dangerous half-truth in so far as it implies that this is the chief or sole *raison d'être* of the illness, and that it will cease as soon as it is made quite clear that there is no chance of this end being achieved. In fact the genesis of these states is complicated in the extreme, and in most cases the neurotic behaviour cannot be stopped by any method known to man.

Wing Cmdr. Bergin's examples are completely unconvincing and indicative of a disarmingly naive outlook. For example, the ability to cycle home and work in the garden with every appearance of pleasure does not in any way suggest that the man's distress when required to work overtime is feigned or exaggerated.

It is obvious that Wing. Cmdr. Bergin has let his judgment and interpretation of the facts be influenced by his moral indignation at the gain which the neurotic may derive from his illness. This gain is a common phenomenon in civilian life also and by no means confined to conditions of military conscription. The only way to prevent this secondary gain in the circumstances would be to gather the neurotics into special units, which would probably serve little useful military purpose and whose chief function would be to keep the personnel on Service pay and living under camp or barrack conditions, so satisfying the code of morality which Wing Cmdr. Bergin advances and which will command widespread approval. These units would require efficient administrative staffs, which would be hardly justifiable from the point of view of the national interest in time of war. The "system" which is castigated is presumably that of invaliding on medical grounds for neurosis. From the moral point of view there is much to be said for the

American system of discharge on the grounds of inaptitude. Not that I personally would agree that our present system is immoral.

The grossly unsatisfactory state of the treatment of neurosis at the present time arises out of the stubborn and intractable nature of these pathological emotional disturbances. Light-hearted superficialities will not help in the solution of this problem.—I am, etc.,

Cheshire. A. Harris, S/Ldr.

Sir,—I have read Wing Cmdr. Bergin's letter, and there is no doubt that his remarks are only too true. It has been my unfortunate lot as a station medical officer to have to deal with a vast number of these cases, and his description and subsequent history are correct in every detail. Many station medical officers with whom I have discussed this type of case are agreed that the approach and handling are wrong, but unfortunately they have no other way of dealing with them. The solution suggested by Wing Cmdr. Bergin—i.e., Do your duty or take the consequence—is of course the solution to the whole problem, but unfortunately it is not so easy as that. I have tried that myself successfully on occasions; but from time to time political influence has been used and instructions issued from higher authority that the patient is to be dealt with in a certain manner. These instructions are issued by someone who has never seen or examined the patient and without consulting the station medical officer. After much thought I have come to the conclusion that the vast majority of these patients are devoid of all sense of duty and are sickened only by selfish thoughts.

The only solution is courage—courage on the part of the medical branch to stand by their convictions; courage among the higher authorities to stand by the medical branch and to say so publicly; and, lastly, courage in the hearts of the weak and selfish to face the slings and arrows.—I am etc.,

G. F. Magurran.

Sir,—Wing Cmdr. Bergin seems to be passing through one of the phases common to medical officers. Even the kindest M.O. is apt to feel annoyed when he discovers what he fancies is a leg-pull, and he naturally relieves his feelings by a more or less indiscriminate outburst of severity, rationalized in whatever way appeals to him. A few M.O.s become congealed in this phase, or its opposite extreme of leniency, but the majority gradually settle down to a middle course as they grow more able to discriminate and less afraid of being wrong. It is perhaps better to be fooled occasionally than to be unjust to an honest man. Even the irritation of being informed—with relish—by a non-medical officer that a man for whose story one has fallen has been heard boasting of his successful deception may be soothed by the reflection that this is by no means proof of malingering.

As to the methods in vogue for separating the wheat from the tares, they fall into three classes: (1) "The Sign from Heaven," otherwise known as clinical intuition or diagnostic acumen. (2) "The Geographical." Certain parts of the British Isles seem to maintain steady streams of "bad eggs" to the Services. Wild horses would not induce me to name my own favourite black spots. (3) "The Police Method," which relies on "information received" and on catching the accused out in contradictory statements.

By a judicious combination of these methods, supplemented by *very* occasional disciplinary action, it should be possible to keep the lead-swinging rate within reasonable limits. The picture that Wing Cmdr. Bergin paints of neurotics "almost without exception" deteriorating steadily and being invalided out is quite outside my experience in the Army. It certainly need not happen, and if it does it must be—in spite of his statement to the contrary—the fault of psychiatrists, unit medical officers, or the executive.

The moral issue, to which your correspondent refers, is simple enough in theory. The measure of a man's sacrifice is the degree to which he disliked making it. War divides people into those who like it and those who don't. Those who like it go willingly, knowing the risks and discomforts; they are the lucky ones, and they have their reward. They make the best soldiers, of course, but to be quite fair they should clearly not be allowed to get away with it; if fairness were the only consideration, they would sternly be directed into offices, factories, or other occupations uncongenial to them, so long as other people are forced into the Army against their will. Fairness, however, must come second to efficiency, and even if it did not it would be impossible to be fair to everybody. And since we cannot claim to be fair, it is difficult to see how we can demand "duty" and "moral responsibility." Such words have their cynical uses, of course. But we like to be fair in our thoughts even if we cannot be fair in our actions (at least we think we like to), and we cannot be so unless we realize that the man whose dislike of service is sufficient to drive him to decisive action, whether that action take the form of desertion, malingering, or the development of neurotic symptoms, is getting, or has had, a raw deal by comparison with his better-adapted comrade. This is no place to enter into futile arguments as to who suffers most—the man who protests or the man who would like to but doesn't. Sufficient has been said to make it clear that moral superiority is not an attitude which becomes us.

The system of which Wing Cmdr. Bergin complains is not intended to encourage escape, but it does recognize the essential pig-headedness of human nature. At a certain point unwillingness converges to inability, for practical purposes, and it pays better to take what the man will give rather than break him because he will not give you all you want.—I am, etc.,

Cambridge. W. E. Hick.

Sir,—I have been reading with interest Wing Cmdr. Bergin's letter. The cases in which he thinks he has failed in that by their "unconscious deception" they have got themselves discharged from the Service are in my opinion his most brilliant results, in that the square pegs have found for themselves the square holes for which by temperament and capabilities they are evidently suited. No work, I think, approaches in quality that which is done happily, with interest, with vim, and from free choice. Disgruntled workers are a potent cause of accidents in that their minds are upon themselves and their grievances rather than upon their work, and thus attention may be lacking at a vital moment.

I cannot emphasize too strongly the misery I have seen caused by labour direction to unsuitable jobs. One girl I know of went out of her mind through being directed away from her home as a mobile worker, which would never have happened if she had been left quietly alone in her factory job (which was turning out war material) in her familiar surroundings. In another case a man used to an open-air life was directed to coal-mining. When I saw him he was a miserable nervous wreck. This state was due to his being coerced into uncongenial employment, and, secondly, to his having seen an accident underground whereby two men were killed.

The tragedy of this war has been that men were forced into occupations for which they were never suited by either temperament or capabilities, and their nervous reserve becoming exhausted shows this by "the well-known features, etc.," which Wing Cmdr. Bergin describes: in other words, the square pegs protest at the round holes, and no amount of jamming them in by harsh discipline or fear will achieve more than a makeshift fit.

There are malingerers, we all know, but these of course are in a different category.—I am, etc.,

Bala. F. M. E. Davies.

Anaesthetic Risks

Sir,—I have read with interest the correspondence on the advantages and disadvantages of spinal anaesthesia. In your issue of Oct. 13 (p. 511) Dr. E. Falkner Hill writes a spirited letter in its defence, but his enthusiasm has led him into making a statement which appears to me questionable: "Inhalation anaesthesia acts by interfering with and to a greater or lesser degree damaging the cerebral cells."

We know, of course, that anaesthetic procedures which deprive the cortex of oxygen for even a comparatively short time do cause permanent damage to the cerebral cells, but does Dr. Hill mean that there is "a greater or lesser degree" of damage even when the oxygen requirements are fully met? If so, it would be interesting to know what scientific ground there is for this statement.—I am, etc.,

Dunfermline, Fife. A. C. Douglas.

Significance of the Erythrocyte Sedimentation Rate

Sir,—Under the heading " Any Questions ? " (Sept. 1, p. 307) the subject of E.S.R. has again been raised. Certain aspects of this problem were fully discussed in the correspondence which followed the paper by Della Vida (1942). In the course of a recent study we have found that confusion largely centres round the following points.

1. *Absence of a Standard Method of Performing the Test.*—Many writers do not state the method they employ. Presumably in such cases the test has been performed according to the original Westergren technique, in which 0.4 c.cm. of 3.8% sodium citrate is added to 1.6 c.cm. of venous blood. This may not necessarily be the case. For example, Dunlop and Dick (1944) employ dry potassium oxalate as an anticoagulant in what they term the Westergren method. Confusion would be avoided by describing the tests as " original Westergren " or " Westergren oxalate."

2. *Employment of Different Anticoagulants.*—Della Vida (1942) and Muller (1943) have drawn attention to the fact that the rate of sedimentation is depressed by dilution of the blood. In a recent series of cases we obtained the following results:

Number of subjects examined	18
Mean second-hour reading (original Westergren method)	22.3 mm.
Mean second-hour reading (dry ammonium and potassium oxalate method)	25.8 mm.

Although the mean value for the oxalate series is greater than that for the citrate series, individual results in the former were not uniformly greater than in the latter. Thus the results for the second hour were as follows: oxalate series greater than citrate series, 12 cases; citrate series greater than oxalate series, 5 cases; both series equal, 1 case. Müller (loc. sit) states that results are influenced according as potassium oxalate and potassium and ammonium oxalate mixture are employed. She cites the opinion of Keen, who found that the readings obtained with potassium oxalate were accelerated and supported the clinical assessment of activity in each case examined, whereas readings with the double oxalate mixture were diminished or within normal range.

3. *Lack of a Uniform Standard of Normal Values.*—There is no agreement as to what constitutes a normal sedimentation rate, even when the same method is used. Westergren adopted the following standard for the one-hour reading: normal, 3 mm.; doubtful, 4 to 6 mm.; probably abnormal, 7 to 12 mm.; certainly pathological, 13 mm. and upwards. Most writers accept as abnormal any reading greater than 10 mm., although Young (1944) regards values as low as 3 mm. in a male and 5 mm. in a female for the first hour as abnormal. Dunlop and Dick (1944), using a 200-mm. Westergren tube and dry potassium oxalate as anticoagulant, regard as abnormal any reading greater than 5 mm. for the one-hour reading.

4. *Disregard of Physiological Variations.*—The consensus is that the only physiological state which causes an appreciable increase in acceleration is pregnancy (Muller, loc. cit.; Wintrobe, 1942), although Obermer (1943) found that some healthy women, for reasons not known, consistently show an increased rate during menstruation. A perusal of Wintrobe's figures shows that, apart from pregnancy, an appreciable number of young adults give readings above the accepted range of normality. Using a mixture of dry ammonium and potassium oxalate as anticoagulant and a 100-mm. tube Wintrobe found that the rate of sedimentation varied from 0 to 6.5 mm. at the end of an hour in 86% of 137 healthy young adult males and from 0 to 15 mm. in 88% of 100 young adult females. He found that the differences were largely accounted for by variations in the haematocrit value, and that when this was corrected to a red-cell volume of 47 c.cm. per 100 c.cm. the rate in 72% of males and females was 0 to 6 mm. and in an additional 16% 7 to 10 mm. for the one-hour reading. There still remains, however, 12% of subjects with a reading greater than 10 mm. We found that 18 of 55 (original Westergren method) and 23 of 62 (dry potassium and ammonium oxalate method) healthy hospital nurses had a one-hour reading greater than 10 mm.

In a group of schoolboys aged 14 to 15 years tested by us 5 of 37 gave a first-hour reading greater than 10 mm. (dry potassium and ammonium oxalate method). On the other hand, among adult male subjects, only 1 of 59 (original Westergren method) and 2 of 76 (dry ammonium and potassium oxalate method) had a one-hour reading greater than 10 mm. The subjects in all these groups were apparently healthy. All had been subjected to a thorough physical examination, although not in every case, at the time the raised sedimentation rate was recorded. Skiagraphic examination of the chest was carried out in each case (on the same day as, or within a few days of, the finding of the raised sedimentation rate), and in none was any abnormality noted. Even if one accepts the hypothesis that the raised rate was due to some occult focus of sepsis, the fact remains that a considerable number of healthy subjects are liable to exhibit accelerated rates—a finding which must always be borne in mind when considered in association with abnormal skiagrams. That an appreciable number of healthy persons exhibit accelerated rates is confirmed by the work of Edwards, Penman, and Blair (1945), who found that the normal sedimentation rate in apparently healthy hospital nurses can be surprisingly rapid. They found that when primary tuberculous infection occurred the sedimentation rate increased considerably. In cases showing a satisfactory response the rate returned to the normal level for the particular subject in about a month. It would thus appear from these results that, in the female subject at least, it is necessary to learn from serial readings the physiological rate for the individual before any conclusions can be drawn from a single estimation.

The opinion is still widely held that the sedimentation rate is constantly raised in cases of active tuberculosis. Kayne, Pagel, and O'Shaughnessy (1939) and Hollins (1942) have even suggested that the test would be of value in the mass investigation of the apparently healthy. Under this arrangement only those subjects showing an elevated rate would undergo x-ray examination. Berrington and Greenwood (1942) employed this method in a mental hospital, and formed the opinion that it is rare to find active tuberculosis with a normal rate. It is difficult to understand how they arrived at this conclusion, since in their scheme active cases with a normal rate would not be examined. When the results obtained by mass radiography are studied an entirely different picture is presented, as the following table shows:

Reference	No. of Subjects with Active Tuberculosis Examined	No. with Abnormal E.S.R.
Stiehm (1933)	69	33
Braeuning (1938)	75	33
Clive (1943)	102	84
Kahan and Close (1944) ..	138	27
Robinson (1944)	45	35
Abeles and Pinner (1944) ..	91	54

It may be argued that, since tuberculous foci may undergo reactivation with considerable rapidity, it is insufficient to claim as active a case showing a normal E.S.R. merely on the strength of changes seen on serial skiagrams. Recently we had the opportunity of performing gastric lavage on the same day as, or within a few days of, the performance of the E.S.R. in seven cases. The former examination gave a positive result in each instance. The one-hour E.S.R. reading was greater than 10 mm. in three cases only, and two of these were females.

In the male subject the test may be of limited value, although the information required by the physician in assessing a case can generally be obtained more accurately without its use. Since in the female subject the test carries an error of anything from 12 to 30% its employment is, for practical purposes, valueless. No other test having an error of this magnitude would be tolerated in practice. Those seeking guidance on the E.S.R. should follow the advice of Hilliard (1942), who " abandoned the use of blood sedimentation tests long ago."—We are, etc.,

"Perspex" in Orthopaedics

Sir,—In his letter (Oct. 13, p. 512) Mr. A. MacGowan levels a great deal of criticism against the article on "perspex" in orthopaedics by Scales and Herschell (Sept. 29, p. 423). I would suggest that he has failed to appreciate that the authors do not advocate "perspex" as a complete substitute for plaster-of-Paris and that they have not recommended that it should be used for short-term cases; surely the list of conditions given, including tuberculosis of the spine and anterior poliomyelitis, consists entirely of those requiring many months of treatment in some form of splint.

He complains that the authors of the article do not make use of the advantages they quote; with this complaint I disagree and instance the following. In the treatment of a case of tuberculosis of the spine with or without sinuses in a young child a "perspex" bed has the following advantages over one made of plaster-of-Paris: it can be washed without deterioration, it needs no absorbent lining, it is non-irritant to the skin, and even Mr. MacGowan must concede the point that it is reclaimable; in treating cases of anterior poliomyelitis "perspex" has the additional advantages that it is light in weight and, being waterproof, it can be worn when doing exercises in the pool.

To give a specific example where "perspex" is of great value I have had some splints made of it for opponens pollicis paralysis, and have a patient with bilateral paralysis who, without the splints, found considerable difficulty in washing, using a tooth-brush, and dressing himself, but when wearing the splints he is able to carry out all these actions easily and comfortably; and added to this the splints are inconspicuous—a factor of great importance, at least to the patient.

Surely no one suggests that "perspex" is a complete substitute for plaster-of-Paris, or that it is the ideal plastic for all selected orthopaedic conditions; but let us at least recognize its advantages, and acknowledge that Scales and Herschell have overcome several obstacles in its use—obstacles which some of the commercial experts considered were almost insurmountable. Further investigations in the use of plastics in orthopaedics are needed and are continuing at Stanmore.—I am, etc.,

Royal National Orthopaedic Hospital, Stanmore. — John A. Cholmeley.

Third-generation Syphilis

Sir,—There appeared a case report by Dr. C. J. V. Helliwell in the *Journal* of Aug. 11 (p. 186) purporting to be one of third-generation syphilis. The boy appears to be a congenital syphilitic, but evidence is lacking to indicate that his mother is. Dr. Helliwell based his case on the negative blood test in her husband, the statement that she never had syphilis, but that her parents died of it. It is not unusual for a woman to be ignorant of ever contracting syphilis. There was no supporting evidence that her parents really died of the disease.

It is recognized that conjugal syphilis occurs less frequently from wife to husband than husband to wife. The age of the infection in the sexual partner is an important factor. Such data as her present age and first sexual exposure were not included in the report.

The occurrence of third-generation syphilis is recognized. Its frequency is unknown, since the facts are not always obtainable. Basic necessary information was not included in the report to justify the conclusion.—I am, etc.,

C. C. Wedderburn, M.B., Ch.B.,
Medical Department, Kingston, Jamaica. — Venereal Diseases Officer.

Infant Feeding and Duodenal Ulcer

Sir,—There is undoubtedly an increase in the incidence of duodenal ulcer at the present time, and it seems to be occurring at a more early age. The custom of feeding infants at four-hourly intervals by day, and of giving no feed at all during the night, began to be taught and rigidly followed after the 1914–18 war. The hungry child very often spends the last hour of the period yelling lustily, while the conscientious parent parades the floor with an eye on the clock until the appointed hour arrives. This must mean that for several hours by day and for a longer period during the night the child's stomach is in a state of anticipatory peristalsis, actively secreting hydrochloric acid, and with probably an accompanying pylorospasm. In a child of sthenic habit this may provide the predisposing factors for the development of ulcer in later life. The remedy would appear to be more frequent feeding of this type of infant by day and permitting a feed during the night.—I am, etc.,

Dundee. — J. M. Morgan.

Housing, Health, and Unwise Spending

Sir,—I would like to supplement Dr. Frewen Moor's comments (Oct. 13, p. 508) on Dr. H. Nelson's valuable paper on housing and health. It is not sufficient to enumerate the common types of unwise spending by the poorer classes; we must try to understand the reasons for it. Take, for instance, the family living in a three-roomed back-to-back or four-roomed dwelling of the type still occupied by probably the great majority of the city working classes. On what can they spend their "surplus" earnings? The cramped squalor of the home precludes the pursuit of any hobbies or cultural or constructive interests of any kind. The more well-to-do family has a garden, spare ground on which to build a workshop, enough rooms and big enough rooms in which to entertain friends or indulge in relaxation. The urban working-class family lives under or on top of another family, or is jammed up on each side with a number of similar families; and they all have children. In addition to the crowding and the squalor there are therefore the ceaseless noise and lack of privacy. The home, in fact, is a place to get away from. In such circumstances *what* can the wage-earner spend money on but cigarettes, cinema, betting, and drink? Even to keep a bicycle may be impossible for want of a place to house it. In my opinion it is of immense importance that this aspect of the life of our poorer classes should be given prominent attention in the planning of our future cities.—I am, etc.,

Birmingham. — E. H. Wilkins.

Training for Released Service Doctors

Sir,—Lieut.-Col. F. F. Hellier in his letter (Oct. 6, p. 477) raises a most pertinent point and one of great import to those in the Services about to be released.

I should like to give my personal experience of applying for a Class III appointment as a registrar in dermatology at a salary of £550 per annum. The necessary form of application was forwarded to the British Postgraduate Medical School and a personal visit made immediately I was demobilized. My qualifications and reasons for applying were stated as follows:

(1) I was keen to become a dermatologist, and at the beginning of the war was hon. assistant dermatologist to the Royal United Hospital, Bath, following the appointment of medical registrar to that hospital. I had not started as a consultant in private and was still in general practice in a town 7 miles away.

(2) I wish to study at the same time for a higher qualification in order to be in a position to apply for hospital staff appointments.

(3) The lease of my house, from which I practised, had been terminated by me in 1943, at the first option (10 years), as I did not intend to return to general practice. I have been unable to sell the practice and there is now only a nucleus which, without a house, appears difficult to sell.

I was informed that I was ineligible under the Government scheme Class III (Registrarship) as I had been established before the war in general practice and had not sold my practice, and would also have been ineligible had I started as a consultant in private. The only class open to me was Class II (14 days' refresher course for general practitioners).

Surely the Government policy is to assist in training men who may later prove useful members of the staffs of hospitals treating large numbers of the community over a period of years, and not to exclude men on technicalities from financial assistance with postgraduate study. The only course open to me now is to do postgraduate study at my own expense, and therefore for a short period (three months) due to financial limitations.

The above facts will, I think, be of interest to those in the Forces who may be trying to work out their post-war plans and are expecting financial assistance from this source.—I am, etc.,

C. D. Evans,
Late Colonel, A.M.S.

Nutritional Macrocytic Anaemia: Correction

We apologize for a misprint in the letter on nutritional macrocytic anaemia by Dr. L. E. Glynn, Prof. H. P. Himsworth, and Dr. A. Neuberger, published last week (Oct. 20, p. 550), by which the word "devoid" was omitted in the seventh line. The sentence should run: "It may therefore be of interest to your readers to know that recently we have found that rats on a diet devoid of methionine develop a macrocytic anaemia characterized by changes in the peripheral blood and in the bone marrow similar to those in human nutritional macrocytic anaemia. . . . The development of this anaemia is not prevented by large supplements of cystine or of iron."

Obituary

W. B. CANNON, C.B., LL.D., M.D.

A wide circle of physiologists the world over will feel a personal loss by the passing, on Oct. 2, of Dr. Walter Bradford Cannon, who for many years held the George Higginson Chair of Physiology at Harvard University. Though a world figure in science, Cannon was essentially a Harvard man, for there he graduated in 1896, and there, with characteristic fidelity, he remained with few interludes until his retirement in 1942, first as instructor in zoology, then in physiology, next as assistant professor of physiology, and finally from 1906 to 1942 as professor.

He was one of the now rapidly dwindling number of all-round physiologists whose inspiration, exerted through generations of pupils, will long continue to be felt, and few scientific men can hope to have both so wide and so beneficial an influence on the evolution of their subject as was his. He brought to his subject not only wide experience and knowledge, but also a broad philosophy, an artistic imagination, and an admirable clarity of expression. His initiation in 1898 (at the age of 27) of the technique of the opaque meal in *x*-ray study of the movements of the alimentary canal was by itself enough to ensure him an important place in the history of the medical sciences. The classical work of Cannon and his collaborators, now generally known, and summarized in his *Bodily Changes in Pain, Hunger, Fear, and Rage*, was an outstanding example of the value of imagination in research, and his book *The Wisdom of the Body* was a further revelation of his wide philosophical outlook on biological phenomena. The accepted theory of the humoral transmission of the nerve impulse has much of its factual foundation in the series of investigations by the Harvard School, led by Cannon.

In the interlude occasioned by the first World War he served in the British Military Service in 1917, and engaged in work on traumatic shock, partly in collaboration with the late Sir William Bayliss. He later became a lieutenant-colonel in the U.S. Army Medical Corps, and served with it till 1919. He was decorated C.B. in 1919, and awarded the Distinguished Service Medal of the U.S.A.

Many other honours and distinctions very properly fell to his lot. Among these were Croonian Lecturer, Royal Society, 1918; foreign member, Royal Society, 1939; Linacre Lecturer, Cambridge, 1930; Baly Medal, Royal College of Physicians of London, 1931; President, American Association for the Advancement of Science, 1940; honorary degrees of Yale, Liège, Strasbourg, Paris, and Madrid; foreign member of several learned academies; Harvard exchange professor, 1929–30; and visiting professor to Peiping Union Medical College, 1939.

He died at the age of 73, after a good deal of ill-health. His calm, happy personality will be remembered with affection by those whose privilege it was to know him.

C. L. E.

T. P. PUDDICOMBE, D.S.O., M.B., D.P.H.

Dr. Thomas Phare Puddicombe, who died suddenly at Great Torrington on Sept. 29, was born in 1877, the youngest son of Robert Puddicommbe of Kilverleigh Manor, Beaford, North Devon. He was educated at West Buckland School, King's College, London, and St. Thomas's Hospital. He served with distinction in France from November, 1914, to May, 1919, in command of the 25th Field Ambulance, with the rank of lieut.-colonel, R.A.M.C. He was thrice mentioned in dispatches and was awarded the D.S.O. Before this he had entered the Local Government Service in 1906 and saw service at Croydon as deputy medical officer of health and at Plymouth as senior medical officer before going to Essex in 1920 to fill the new post of deputy county medical officer of health in 1930. Thus when he retired in 1942 he had seen 35 years' service with local authorities, 22 of which had been spent with the Essex County Council.

Dr. W. A. Bullough writes:

When we in Essex heard of his death our minds went back to the day he left us in March, 1942, when so many good things were said about him by all ranks in the service, from the chairman of his committee to the humblest member of the clerical staff of the Public Health Department. His own quip (he was full of quips and pleasantries) on this occasion was that he felt like a man attending his own funeral, because that was when most nice things were said about people. We feel some pleasure that we were able to say these things to his face and have not left them all to be said after he is dead. His geniality, kindness, sympathy, and consideration will long be remembered by those who came into contact with him, particularly a very wide circle of parents in Essex, who have much reason to be grateful to him in his capacity as mental expert for his tact and kindness. If there was a problem to be solved that involved the human element, official or unofficial, "Tay Pay" (as he was affectionately known) was the man to solve it, and he is gratefully remembered as a guide, philosopher, and friend by many in Essex. Those who were privileged to visit him in his bungalow in Rothesay Avenue, Chelmsford, saw the foundation of his character—a great home lover, one who was proud of his home and his garden. He was keen on indoor and outdoor sport—he founded and was the moving spirit in a Badminton Club in Chelmsford. Whatever the game, he played with enthusiasm and vigour. Truly he was a leader of men in more ways than one.

Personally, I was most indebted to him for his great loyalty. No matter how much we disagreed, one could always depend upon "Tay Pay" to be loyal to the extreme. His industry amazed me; quietly and methodically he got through an immense amount of work. And, above all, I admired and liked him for his straightforwardness. If he disagreed he said so, and that was the end of it. One always knew that what he said he meant. I always found him willing to do anything, and he had that inestimable characteristic which made him an ideal deputy—a complete absence of self. I never had any fear about the School Medical Service in Essex under his control, and he never let me down. In his capacity as mental expert I never found a flaw in his diagnoses and estimations.

Outside Essex he had many interests. He was a Fellow of the Society of Medical Officers of Health, and for many years represented the School Medical Group on the executive committee of the society. He was a member of the Central Association for Mental Welfare, and was also keenly interested in the Essex Rural Community Council, and was, in fact, chairman of the health committee for many years. He also gave much attention to the scheme for the preservation of rural England. He was greatly missed by the council when he left Essex. He told us that he intended to live the life of a country gentleman in the West Country when he retired, and we felt that there was no one more fitted to do so. Some of us were privileged to spend short wartime holidays with him among his own folk. It is fitting, indeed, that he should have died in his own beloved Devon. To his wife and son, Capt. Robert T. M. Puddicombe, R.A.M.C., who arrived home on leave from Italy just too late to see his father alive, we extend our deepest sympathy.

Dr. Gerald Quin Lennane, who held the post of M.O.H. for the metropolitan borough of Battersea from 1906 to 1934, died on Sept. 12 after a long illness. He was born at Galway in 1869, and after qualifying in Dublin in 1891 went to sea as a ship surgeon, and then took the F.R.C.S.I. and the D.P.H. in 1900. In 1914, at the age of 45, he volunteered for a commission in the R.A.M.C., served in France, was mentioned in dispatches, and awarded the Military Cross in 1917. After returning to civil life he was for 16 years examiner in hygiene at the R.A.M. College, and Battersea Borough Council named a block of flats after him in recognition of his long and valuable service. Dr. James Fenton in the course of a tribute in the *Medical Officer* has written: "It was Lennane's custom to get in touch with young men on their first taking up an appointment as M.O.H. of a metropolitan borough and offer his advice and experience in any problems which might present themselves to the newcomer. This approach was always made in a kindly way, and was often associated with Lennane's well-known hospitality. The only reward he wanted was the knowledge that he might occasionally be of some help. In debates at meetings of the Metropolitan Branch of the M.O.H. Society and at his club he displayed an old-world courtesy which endeared him to his wide circle of friends. In Battersea he was highly respected by his councillors for the courageous way he tackled many public health problems."

We regret to record the death on Sept. 14 of Dr. George Hall of Stockton-on-Tees, at the age of 66. He was born at Macduff, Banffshire, and educated at Banff Academy Grammar School and at King's and Marischal College, Aberdeen. At Aberdeen University he graduated M.A. in 1900, proceeding M.B., Ch.B. in 1905. He had been a member of the B.M.A. for nearly forty years, contributing an article on "Spontaneous Inversion of the Uterus" to the *Journal* in 1908. Having travelled round the world after completing his studies he took up practice in Stockton. For 38 years he was in close touch with the Stockton and Thornaby Hospital, being appointed hon. surgeon in 1918, and continuing on the honorary staff until 1944, after having served five extra years at the request of the hospital committee. He was chairman of the Stockton Division of the B.M.A. from 1929 to 1931 and an important member of the committee of the North of England Cancer Research Campaign for many years. A colleague writes: Not merely as physician and surgeon will George Hall be missed in the whole district but as a beloved friend. He was a humble, reticent, and tireless worker in the community, being held in high esteem and affection by colleagues and townspeople alike, countless of whom owe their well-being and very lives to his skill and unbounded devotion to duty. A gloom has been cast over thousands by his passing and he will be sorely missed by his patients and friends.

Mr. Ralph Marsh de Mowbray, F.R.C.S., of Lymington, Hants, who died on Sept. 24, had been for many years surgeon to the Lymington Cottage Hospital and the Milford-on-Sea War Memorial Cottage Hospital, and consulting surgeon to the Fenwick Cottage Hospital at Lyndhurst. Born at Vinossington on Oct. 16, 1887, son of the Rev. J. H. M. de Mowbray, he entered St. Thomas's Hospital in 1905 from Marlborough College and qualified in 1914, taking soon afterwards the F.R.C.S. During the war of 1914–18 he served first for a year at the British Red Cross Hospital at Netley, and then for over three years, with the rank of captain, R.A.M.C., as surgical specialist and officer in charge of the surgical division of No. 34 General Hospital at Deolali, India. Mr. de Mowbray had also been house-surgeon, casualty officer, and resident anaesthetist at St. Thomas's Hospital, and house-surgeon at the Royal Hants County Hospital, Winchester. He joined the British Medical Association in 1919.

Dr. David Johnston Jones, who died at Llandudno on Sept. 24, aged 91, was educated in Edinburgh, London, and Paris, graduating M.B., C.M.Ed. in 1876, and M.D. in 1879. After serving as house-surgeon at the Liverpool Royal Infirmary he became senior assistant medical officer to the Kent County Mental Hospital, near Maidstone, and was then for a long time medical superintendent of the L.C.C. Mental Hospital, Banstead. Dr. Jones joined the British Medical Association in 1880. At the date of his death there were only three living members with as long a membership of the Association, though 66 years is not a record, the late Sir James Crichton-Browne having remained in membership for 69 years.

Dr. William McDougall, who died on Sept. 29, had practised for 48 years at Wallington, in Surrey. The son of a Highland minister, he went to school at Aberdeen and then to the University of Edinburgh, where he graduated M.B., C.M. in 1889. After a sea voyage, and a house appointment in Carlisle, he settled in the remote township of Tongue, on the north coast of Scotland. His work there demanded journeys on horseback as far as forty miles from home, over wild country: a single visit to a patient with pneumonia would sometimes take him two days and a night. After his first marriage he came south to a very different kind of practice in a village two or three miles from Croydon, where something of a Scottish community was forming round the Presbyterian church. In half a century Wallington grew out of recognition, and Dr. McDougall, having started work alone, eventually became the senior partner of a firm of four. In 1913 he had joined forces with Dr. A. T. Moon, F.R.C.S., and in 1916–17 he was able to spend a year in the R.A.M.C. at the Connaught Hospital, Aldershot. From the foundation of the Carshalton War Memorial Hospital, about 1923, he was a member of the active staff until he became consulting physician ten years ago. "He was," writes a colleague, "a first-class physician, painstaking to a degree. Restrained and even dour with strangers at first, he had a friendliness and understanding which stirred the affection of his patients into a devotion deep and abiding. He was a man of unalterable integrity whose whole life was a service to his fellows, carried to the full and to the end. His rare and deep humour, his generosity to all in need, and the religion he lived so thoroughly, made him an example which his friends must always remember, and which must always influence them." Dr. McDougall died at 79 years of age, having doggedly continued his work throughout the war. He leaves a widow and two sons and two daughters.

Dr. James Cecil Mottram, director of the research laboratories of Mount Vernon Hospital, Northwood, died on Oct. 4 at Northwood. He was born at Holt, Norfolk, on Dec. 12, 1880, only son of James Mottram, and was educated at the Beacon School, Sevenoaks, University College and Hospital, London, and St. John's College, Cambridge. He graduated M.B.Lond. in 1903, and took the D.P.H.Camb. in 1906. After working as first assistant at the Ayr County Asylum and bacteriologist for the County of Worcester he became first assistant in the cancer research laboratories of the Middlesex Hospital. During the war of 1914–18 he served as lieut., R.N.V.R., attached to the Royal Naval Experimental Station, Stratford, and advisory expert at the Camouflage School, G.H.Q. After returning to civil life Mottram was appointed director of the research department of the London Radium Institute, and continued in that post when the Institute joined up with the Mount Vernon Hospital at Northwood. He made numerous reports to the Royal Society, to the Royal Society of Medicine, the Linnean Society, the Zoological Society of London, and the Pathological Society, on cancer, radiology, and animal coloration. The last-named subject was, with fly-fishing and the study of trout and trout fisheries, Mottram's principal hobby. He wrote articles on animal coloration and on camouflage for the *Encyclopaedia Britannica.*

Dr. Ernest Le Cronier Lancaster, formerly a leading member of the profession in Swansea and well known as a naturalist, died at Lyme Regis, Dorset, on Oct. 4, in his 84th year. After taking his B.A., with first-class honours in science, at the University of Oxford in 1883, he went to St. George's Hospital for his clinical course, graduating M.B., B.Ch. in 1887. At St. George's he served as house-physician, resident obstetric assistant, and demonstrator in anatomy and physiology. He became physician to the Swansea Hospital, to the Aberavon and Port Talbot General Hospital, and to the Swansea and South Wales Institute for the Blind, and he attained the rank of lieut.-colonel, R.A.M.C.(T.). Dr. Lancaster joined the B.M.A. in 1892, was elected chairman of the Swansea Division in 1910, and president of the South Wales and Monmouthshire Branch in 1914. He was a past-president of the Swansea Medical Society, a J.P. for the County of Glamorgan, and for many years acted as honorary curator of the local museum; in retirement he undertook the same duty for Lyme Regis. Two branches of zoology attracted him most—the study of shells and shell-fish, and the study of molluscs—and he was for many years an active member of the Conchological Society of Great Britain and Ireland and of the Malacological Society of London. His professional writings were several papers in the *Transactions of the Clinical Society* during the 'nineties, and a paper on heredity and disease published in these columns in 1910.

Dr. James Macdonald Troup, consulting physician to the Pretoria Hospital and the doyen of the medical profession in that city, died on July 31 in his 78th year. A native of Huntly, in Scotland, he was the youngest son of the Rev. Robert Troup, and after early education at Madras College went to St. Andrews University, where he graduated M.A. with honours in 1887. He won the Guthrie Scholarship from St. Andrews to Cambridge, was 7th Wrangler in the Mathematical Tripos of 1890, and went on to King's College Hospital, London, with a senior scholarship. He took his M.B., B.Ch.Camb. in 1896, and was house-surgeon at King's to Watson Cheyne. In the following year he went to South Africa to an appointment at Grahamstown, and later for a time practised at Somerset East. He settled in Pretoria in 1902, and during 43 years there his life was devoted to his patients; he soon gained a reputation for sound judgment and for skill in diagnosis and treatment; moreover, he was one of those practitioners whose advice and counsel were sought on many personal matters outside the strict range of his profession. The *South African Medical Journal* has published a number of tributes to Dr. Troup from colleagues, and a long appreciation of his character and gifts and his attitude towards the science and art of medicine by Dr. A. Pijper, written from 25 years' personal knowledge. One passage may be quoted here: "Troup had a persuasive manner and his authority was readily accepted. He was a marvellous diagnostician and had a horror of mechanized medicine, as it is called. Yet he used the laboratory to the utmost, but it was merely to confirm his ideas or to give him the needed quantitative data. If he had to subject a patient to more than one 'test' he blamed himself. Difficult cases were first discussed with the pathologist, on equal terms. Working with Troup was a delight to the laboratory-man. Even in the early days large numbers of his patients had laboratory work performed, and this being unusual in those days, I once asked him how the patients took it and whether it did not detract from his status. He countered by saying that the opposite was the case: his patients realized the purpose and that their doctor was on the right track." Dr. Troup had been a member of the British Medical Association since 1897.

Universities and Colleges

ROYAL COLLEGE OF SURGEONS OF ENGLAND

Lister Memorial Lecture

Sir Howard Florey, F.R.S., delivered the Lister Memorial Lecture at the Royal College of Surgeons on Oct. 11, taking as his subject "The Use of Micro-organisms for Therapeutic Purposes"; it will appear in a future number of the *British Medical Journal*. At the end of the lecture he was presented with the Lister Medal for 1945 which had been awarded to him for his distinguished contributions to surgical science.

A quarterly meeting of the Council of the College was held on Oct. 11, with Sir Alfred Webb-Johnson, Bt., President, in the chair.

A Diploma of Fellowship was granted to David Barrett Feather (Leeds Medical School).

Diplomas of Membership were granted to the following successful candidates: W. H. Lonsdale, E. C. Hutchinson, P. M. Jeavons, C. H. de Boer, Lucy M. Dunkerley, R. L. Greenwood, H. Wainstead, H. A. Lane.

Diplomas in Physical Medicine were granted jointly with the Royal College of Physicians of London to F. J. Bach and E. J. Crisp.

Diplomas in Child Health were granted jointly with the Royal College of Physicians of London to the following successful candidates: H. I. C. Balfour, H. Blair, Agnes A. Brash, E. H. Brown, E. F. B. Cadman, A. Comfort, Nancy D. Cox, J. G. Dathan, R. L. J. S. Derham, Glenys M. M. Donaldson, F. R. M. Elgood, Elizabeth de C. Falle, I. W. Gallant, Susanna Gordon, Mona Griffin, G. R. Griffith, Ursula Jerram, A. Kahan, Margaret Kemsley, Vivien U. Lutwyche, Helen M. C. Morley, Joan L. Noak, G. E. Paget, Margaret Pardoe, H. E. Parry, P. E. Polani, Phyllis Poyner-Wall, L. S. Prasad, R. J. P. Pugh, Mary M. E. Rutter, Vivian M. N. Usborne, D. E. Yarrow, S. S. Yudkin, C. Zahra Neumann, H. L. Zondek.

A Leverhulme Research Scholarship was granted to Mr. P. B. Ascroft, F.R.C.S., for research on the pathology of head injuries.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH

Dr. J. A. Nixon, Emeritus Professor of Medicine in the University of Bristol, will deliver the Dr. Alexander Black Lecture on "The Health and Safety of the Merchant Seaman" at the College (9, Queen Street, Edinburgh) on Friday, Nov. 2, at 4 p.m. The lecture is open to all graduates and senior students.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH

At the annual meeting of the College, held on Oct. 17, the following officers were elected for the ensuing year: *President*, Mr. J. M. Graham. *Vice-President*, Prof. R. W. Johnstone. *Secretary and Treasurer*, Mr. K. Paterson Brown. *President's Council*, Sir John Fraser, Bt., Dr. G. Ewart Martin, Mr. Francis E. Jardine, Mr. W. Quarry Wood, Mr. Walter Mercer, Prof. J. R. Learmonth. *Representative on the General Medical Council*, Mr. Henry Wade. *Convener of Museum Committee*, Mr. W. Quarry Wood. *Librarian*, Dr. Douglas Guthrie.

At a meeting of the College held on Oct. 17, with the President, Mr. J. M. Graham, in the chair, the following, having passed the requisite examinations, were admitted Fellows: J. Boyes, A. E. Bremner, J. A. Chalmers, A. W. Chambers, Prudence Halton, J. A. Harpman, G. Hay, W. A. N. Inglis, E. M. Innes, Alberta M. Jeans, Kathleen M. Long, R. N. Martin, D. Telford, N. Whalley.

The Services

Lieut.-Col. (Temp.) H. Rees and Major (Temp.) S. K. Datta, I.M.S., have been mentioned in dispatches in recognition of gallant and distinguished services in the field.

The following appointments and awards have been announced in recognition of gallant and distinguished services in North-West Europe:

C.B.E. (*Military Division*).—Brig. (Local) E. Bulmer, O.B.E., Brig. (Acting) J. T. McConkey, and Col. (Temp.) F. A. Bearn, D.S.O., M.C., R.A.M.C.

O.B.E. (*Military Division*).—Cols. F. G. Flood, M.C., and R. G. Shaw, M.C., late R.A.M.C.; Cols. (Acting) J. P. Douglas, M.B.E., and F. McL. Richardson, D.S.O.; Cols. (Temp.) J. P. J. Jenkins, T.D., H. E. Knott, and G. G. Talbot, T.D.; Lieut.-Cols. (Temp.) J. C. Anderson, W. S. C. Copeman, R. Evans, F. N. Foster, T.D., E. Hutcheon, A. B. Kerr, T.D., and W. R. Logan, T.D., R.A.M.C.; Cols. C. F. Abbott and C. G. Wood, Lieut.-Cols. D. Campbell, K. J. Coates, C. D. S. Leef, and J. Tanzman, R.C.A.M.C.

M.B.E. (*Military Division*).—Major R. B. Hunter, Majors (Temp.) D. J. Johnson, W. Michie, R. O. Murray, and R. O. G. Norman, and Capt. K. C. Burrow, R.A.M.C.; Majors W. A. McKibbon and E. Wolstein, R.C.A.M.C.

D.S.O.—Lieut.-Col. (Temp.) M. W. Gonin, R.A.M.C.

M.C.—Major (Temp.) J. L. Chisnall, Capts. R. D. S. Jack, G. D. H. McQuitty, I Morris, and J. Sheehan, and Lieut. R. W. Major, R.A.M.C.; Capt. K. A. Campbell, R.C.A.M.C.

The following appointments and mentions have been announced in recognition of distinguished services during the liberation of prisoners from German concentration camps.

O.B.E. (*Military Division*).—Lieut.-Col. (Acting) F. S. Fiddes, Lieut.-Col. (Temp.) J. A. D. Johnston, M.C., and Lieut.-Col. F. M. Lipscomb, R.A.M.C.

M.B.E. (*Military Division*).—Capts. P. O'Donnell and D. B. Peterkin, R.A.M.C.

Mentioned in Dispatches.—Major H. A. Tuck; Majors (Temp.) E. M. Griffin, G. M. C. Smith, and D. J. Waterston, M.B.E.; Capts. G. M. Baker, I. Gluck, J. Kraus, D. T. Prescott, and W. C. Winterbottom; Lieuts. S. Durrant and N. Winter, R.A.M.C.

Repatriated.—Major J. W. D. Bull, R.A.M.C.

Dalkeith Presbytery, in Midlothian, has sanctioned the erection in Newbattle Parish Church of a three-light stained glass window to commemorate the members of the R.A.M.C. who were stationed at Newbattle Abbey in the early years of the war.

Medical Notes in Parliament

On Oct. 18 the Parliamentary Medical Group met at the House of Commons and elected Dr. Haden Guest as chairman, Mr. Hugh Linstead as hon. secretary, and Sir Henry Morris-Jones as hon. treasurer. The Group decided to meet monthly. Its next meeting will discuss demobilization. Dr. Haden Guest was re-elected the representative of the Group on the Central Medical War Committee.

The Parliamentary Medical Committee of the Labour Party, under the chairmanship of Mr. Somerville Hastings, will work in close co-operation with the Health Group of the party.

Distribution of Medical Man-power

Mr. Lawson stated on Oct. 16 that the present ratio of R.A.M.C. medical officers in the Forces to personnel under their medical charge is 2.57 per 1,000. All effective medical officers, whether engaged on administration, hygiene, hospital work, or attendance on unit sick, are included in the ratio. The present proportion of doctors of all kinds in this country to the civilian population is 0.74 per 1,000. He added that circumstances and conditions in the Army and civil life are so different that any true comparison is impossible.

Sir Gifford Fox on Oct. 17 asserted that the present strength of medical officers in the R.A.F. was 2.27 medical officers per 1,000 men, which compared with one doctor per 3,500 of the civil population. He asked why it was necessary for the proportion of doctors in the R.A.F. to be eight times that for the country as a whole. Mr. JOHN STRACHEY replied that the ratio given for the Air Force included doctors employed in hospitals on research and on administration as well as those on R.A.F. stations at home and abroad. On the other hand, the civilian figure for this country, which was about 2,500 per doctor, and not 3,500 as stated in the question, related to general practitioners, and excluded doctors working only in hospitals, on public health administration, and on research. A similar figure for the Air Force would be 1 in 1,000, out of which provision has to be made for a doctor at each active airfield. This ratio was less than was provided in peacetime. The distribution of medical man-power is now under review by the Government.

No. 30 General Hospital

Answering an inquiry by Sir John Mellor on Oct. 9, Mr. LAWSON reported that No. 30 General Hospital was sent to Norway on June 6, 1945. Its purpose was, in conjunction with other medical units, to provide for the care and treatment of the Allied occupation force and liberated Allied prisoners of war. He said 125 in-patients and between 300 and 400 out-patients were treated together with 559 dental cases. The records relating to out-patients were not available in the United Kingdom. The in-patients and dental cases were wholly Allied and mainly British. The total strength of the unit was 23 officers (including 18 R.A.M.C.), 40 nursing officers, and 159 others. The unit returned to the United Kingdom on Aug. 3, 1945. Mr. Lawson pointed out that when the unit was dispatched to Norway it was not known what difficulties would be encountered by the occupying force.

Release of Students

Mr. ISAACS stated on Oct. 9 that students eligible for release from the Forces in Class B include students in medicine, dentistry, and veterinary surgery recommended by the universities or the appropriate schools if these students had: (1) given up their reservation to join the Forces; or (2) joined the Forces before the present conditions of reservation were in operation, but would have been reserved if these had been in force. Only men in release groups 1–19, with substantially three years' service, were eligible. Mr. Isaacs added that he was not prepared to alter his policy for students who left the universities in the summer of 1945. Those who entered the universities in Oct., 1944, and subsequently could take a full course.

Britain and the Atom

Mr. ATTLEE said on Oct. 9 that the United Kingdom Government will be happy to share with the United States and Canada, and then with other nations, with the object of agreement on co-operation, in the development of atomic energy. The Government was pursuing its own studies through the Advisory Committee.

Cancer Statistics

A table issued by Mr. BEVAN on Oct. 11 shows that the death rates per million living (civilians only) from all forms of cancer in England and Wales during the years specified were as follows:

	Actual	Standardized
1940	1,723	981
1941	1,780	979
1942	1,834	977
1943	1,899	983
1944	1,897 (Provisional)	Not available

The standardized death rates are those which would have been recorded if the sex and age constitution of the population had been the same as in 1901.

Release of Naval Medical Officers

Mr. A. V. ALEXANDER in a written reply in the House of Commons on Oct. 12 said that until certain factors were known it would not be possible to give definite information regarding the release of naval medical officers. These factors were: complete information about wounded and invalids on distant stations, or naval personnel who had been prisoners in Japan; what arrangements could be made for bringing these patients home: and the number of doctors that could be recruited into the Navy in the coming months. The Admiralty expected to release Groups 9 to 19 by the end of 1945, and up to Group 30 by the end of June, 1946. At this rate release of medical officers would be only one or two groups behind the average rate for naval officers.

Tuberculosis: Accommodation in Sanatoria.—Mr. BEVAN stated that the number of patients awaiting admission to sanatoria is about 5,000. Above 1,600 existing tuberculosis beds are closed for lack of staff. A sufficiency of additional accommodation could be provided without much difficulty if staff for it were available.

Invaliding from the Far East.—In a written reply on Oct. 9 Mr. LAWSON recorded that the decision as to which individuals should be evacuated from the Far East on medical grounds was in general left to the medical authorities on the spot, who alone were in a position to assess all the factors in each case. The disposal of patients suffering from tropical illnesses had been carefully considered from time to time in the War Office and general policy defined. The majority of patients made complete recovery from tropical illnesses such as malaria and bacillary dysentery. Patients were invalided home when suffering from complaints which render continuation of service in the Tropics inadvisable.

Medical News

Sir Arthur MacNalty will give the Thomas Vicary Lecture on "The Renaissance: its Influence on English Medicine, Surgery, and Public Health" at the Royal College of Surgeons of England on Nov. 1, and Mr. C. Max Page the Bradshaw Lecture, entitled "A Survey of Fracture Treatment," on Nov. 8. Both lectures will be given at 5 o'clock.

A general meeting of the Paddington Medical Society will be held at St. Mary's Hospital, W., on Tuesday, Oct. 30, at 8.45 p.m., when Dr. H. L. Marriott will deliver a lecture on "Medical Progress during the War."

The annual general meeting of the Association of Anaesthetists of Great Britain and Ireland will be held at the Royal College of Surgeons of England (Lincoln's Inn Fields, W.C.) on Wednesday, Oct. 31, at 2 p.m. A film show will follow at 4.30 p.m. and, at 7 p.m., dinner in the College. On Thursday, Nov. 1, at 10 a.m., there will be clinical demonstrations.

No fees and no tickets of admission are necessary for the post-graduate course in rheumatism to be held by the Empire Rheumatism Council from Oct. 31 to Nov. 11, inclusive, at B.M.A. House. Details of the course were announced in the *Journal* of Oct. 13 (p. 516).

Prof. James Gray, F.R.S., will give a series of four lectures on "The Anatomy and Functions of the Brain in Lower Vertebrates" before the Royal Institution (21, Albemarle Street, W.) on Thursdays, Nov. 1, 8, 15, and 22, at 5.15 p.m.

A course of four lectures in celebration of the 50th anniversary of the discovery of *x* rays will be delivered by Dr. A. Müller and Mrs. Kathleen Lonsdale, D.Sc., F.R.S., before the Royal Institution (21, Albemarle Street, W.) on Tuesdays, Nov. 6, 13, 20, and 27, at 5.15 p.m. On Nov. 6 and 13 Dr. Müller will discuss "The Background of Röntgen's Discovery" and "After the Discovery of *X* Rays," and on Nov. 20 and 27 Dr. Lonsdale will speak on recent research work in the Davy Faraday Laboratory on "Atomic Movements in Crystals" and "Divergent Beam *X*-ray Crystallography."

A meeting of the Medical Society of the L.C.C. Service will be held at the Archway Histological and Group Laboratory, Archway Road, Highgate, N., on Wednesday, Nov. 7, at 3 p.m. The meeting will be devoted to pathology.

The annual general meeting of the British Medical Students' Association begins to-day (Friday, Oct. 26) at B.M.A. House, Tavistock Square, W.C., with an address by Lord Moran at 3 p.m. Guy's Hospital Students' Union has invited delegates and visitors to a dance in the evening. Business meetings will occupy Saturday morning and afternoon; Prof. J. A. Ryle will speak at 4.15 p.m. on "Social Pathology." During the evening a programme of medical films will be presented. Election of officers will take place on Sunday morning, to be followed by a discussion on plans for the coming year. Tickets have been booked for a concert by the London Philharmonic Orchestra in the afternoon. All sessions are open, but as accommodation is limited preference will be given to delegates and other members of the Association.

The annual general meeting of the Association of the Honorary Staffs of the Major (Non-teaching) Voluntary Hospitals of England and Wales will be held at the Royal College of Surgeons of England (Lincoln's Inn Fields, W.C.) on Friday, Nov. 9, at 2.15 p.m.

Dr. R. W. Durand has now returned from his service with the R.A.F., and has resumed his duties as secretary of the London and Counties Medical Protection Society, Ltd.

Dr. Joseph Victor Landor and Dr. Robert Kenneth McAll have been released from internment in Japanese hands.

A sessional meeting of the Royal Sanitary Institute will be held at Weston-super-Mare Town Hall on Saturday, Nov. 3, at 10.15 a.m., when papers will be read by Dr. C. G. Eastwood on "David and Goliath: A Plea for the Individual in Social Medicine" and by Dr. T. L. Scott on "The Movable Dwelling: Is it adequately Controlled?"

On Nov. 7 the Medical Sickness, Annuity and Life Assurance Society, Ltd., will move its head office from Cirencester to 7, Cavendish Square, London, where its new business department is already installed and inquiries can be dealt with.

Three cinematograph films on children's health, which will be available for non-theatrical showing from Nov. 1, mark a new departure in the long series of films made by the Ministry of Information for the Health Departments. They are intended particularly for parents and for all who have charge of children. They embody sufficient elementary physiology to explain the structure and working of the organs treated and to show why certain simple health precautions are important. Diagrams play a leading part in presenting the principles of structure. "Your Children's Eyes" runs for 19 minutes, "Your Children's Ears" for 17, and "Your Children's Teeth" for 15. As they are all sound films they cannot be used on a silent projector. They are available in both 35 mm. and 16 mm. They can be shown in any part of the country, by means of the Ministry of Information Mobile Units, to parents' and teachers' organizations or at meetings arranged by any organizations interested in health. They can also be borrowed, by any organization which has its own sound projector, from the Central Film Library, London, the Scottish Central Film Library, or the Film Library at Dartington Hall, Devon. Medical officers of Health may apply for these films from the Central Film Library through the Central Council for Health Education, Tavistock House, Tavistock Square, W.C.1, which can also arrange talks or lectures as part of the programme.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* during the week the only diseases which showed very much change in incidence were scarlet fever, which increased by 174, and dysentery, which fell by 57 cases. The largest variations in the totals of diphtheria were increases in Lancashire 14, and Warwickshire 10, and a decline of 16 in Glamorganshire. There were 29 fewer notifications of whooping-cough in Yorks West Riding, and 20 more in Middlesex, than in the previous week. The notifications of measles were the lowest since it became notifiable; during the week one-quarter of the total cases were recorded in Lancashire. Four of the 15 cases of typhoid were reported from the metropolitan borough of Woolwich.

The total for dysentery has decreased for the third consecutive week. The largest returns were London 56, Lancashire 34, Surrey 19, Yorks North Riding 16.

In *Scotland* notifications of scarlet fever increased by 46, and of diphtheria by 33; there were 25 fewer notifications of acute primary pneumonia, 15 fewer of measles, and 14 fewer of whooping-cough. The rise in diphtheria was mainly in the west; the largest local rise was Glasgow 11, and in this city, also, scarlet fever rose in incidence from 64 to 100 cases. Although the total for dysentery increased by only 9, the two principal centres of infection showed rises from 12 to 19 in Edinburgh, and from 57 to 66 in Glasgow.

In *Eire* the infectious diseases of childhood were more prevalent. Diphtheria notifications were up by 42, whooping-cough by 44, and measles by 18. The higher incidence of diphtheria was general throughout the country. The two large centres of infection for whooping-cough were Clare, Killadysert R.D. 27, and Dublin C.B. 20. The notifications of diarrhoea and enteritis fell by 48, and the total, 62, was the lowest for the past eight weeks.

Quarterly Returns for Northern Ireland

Births registered in Northern Ireland during the second quarter of this year numbered 7,509, equivalent to a rate of 22.8 per 1,000, or 2.5 below the rate for the June quarter of 1944 and 1.4 below the average rate for the second quarters of the five years 1940-4. Infant mortality was 67 per 1,000 registered births, compared with 60 for the corresponding quarter of last year and 72 for the average of the second quarters of the five preceding years. Maternal mortality was 2.8 per 1,000 births, and 1.0 below the average rate for the five preceding June quarters. The general death rate was 12.0 per 1,000, being 2.2 below the five-years average. Deaths from infectious diseases included diarrhoea and enteritis under 2 years 58, whooping-cough 22, influenza 21, diphtheria 10. Pulmonary tuberculosis was the cause of 216 deaths, and other forms of tuberculosis 82, these numbers being 24 and 2 respectively below the average for the five preceding second quarters.

Week Ending October 13

The notifications of infectious diseases during the week in England and Wales included: scarlet fever 1,849, whooping-cough 970, diphtheria 565, measles 446, acute pneumonia 415, cerebrospinal fever 36, acute poliomyelitis 45, dysentery 286, paratyphoid 6, typhoid 10.

No. 40

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Oct. 6.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

---

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to movements of population, birth and death rates for Northern Ireland are still not available.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Aitiology Westcent, London.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ANY QUESTIONS?

Intermarriage of White and Black

Q.—*The story has been going round of a white girl who married a white American and gave birth to a coal-black baby; subsequent investigation showed that one of the husband's very distant ancestors had been a negro. I tell my patients that if the negro ancestors were so far back that the man was white, then his baby could not possibly be coal-black, but I really do not know whether this is true. I also tell them that if a white man or woman marries a negro and has a lot of children, they will not be some pure white, some pure black, and some brown, and I tell them that none of the children will be piebald. I should be glad of information.*

A.—The story has been going around for a very long time—probably for hundreds of years. The questioner is right in doubting it. A white girl and a man who passed for white, though actually of remote negro ancestry, could not have a black baby. The only element of fact which might account for such beliefs is that two persons, both of whom had negro ancestry (and not very remote at that) but who were themselves sufficiently light perhaps to pass for white, might have a child of medium colouring. Davenport, whose valuable monograph *Heredity of Skin Colour in Negro-White Crosses* (Carnegie Inst. of Washington, Publication 188, 1913) should be consulted, states: "At Jamaica I asked several highly intelligent coloured and white natives if they knew of cases of 'reversion' to black skin colour. All replies agreed in holding the idea mythical," so that apparently the story is not accepted, even popularly, in areas where crossing is frequent and there are abundant opportunities for observation. Perhaps some of Davenport's intelligent observers recalled the anecdote which is a sufficient commentary on another myth.. A very dark-skinned lady explained how before her birth her mother had been greatly frightened by a black man who chased her down the street; to which the unsympathetic response was: "I guess he caught her."

The questioner is also right in telling his patients that the offspring of a negro-white marriage show relatively little segregation; the resulting mulattos tend to be of medium colour and variation is not wide. As would be expected if only a few main genetic factors were operative, there is much more variation amongst the offspring of mulattos who marry each other. In all probability Davenport's hypothesis of two main factors, if we allow for certain complications and add further minor quantitative factors and non-genetic variations, accounts for the facts reasonably well. Inherited "piebalding" is something quite different and is due to a dominant gene. It may appear in black or in white persons, though it is naturally much more striking in the former.

Increasing Weight

Q.—*It is frequently difficult in persons who are under weight to bring about any increase, although they are apparently healthy and no signs can be found to indicate disease. I would appreciate advice regarding methods recommended.*

A.—Of course it is important to exclude organic disease, and, apart from clinical examination, *x*-ray of the chest, blood count, and sedimentation rate should be undertaken. It is also assumed, in answering the question, that such endocrine disorders as thyrotoxicosis, Simmonds's disease, and Addison's disease have been excluded. After this, the most important cause of failure to gain weight, or of loss of weight, is psychological, not only as an obvious anorexia nervosa but in less tangible form. For this reason the psychotherapeutic approach should never be neglected. Providing there is no evidence of hypoglycaemia, insulin often proves useful—10 units of simple insulin ten minutes before breakfast and ten minutes before lunch. It is usually unwise to give it at night, in case a hypoglycaemic reaction occurs. In males testosterone has an anabolic effect, and the same is relatively true of oestrogens in women, but here one may have resulting disturbance of menstruation, and the water-retention factor may become troublesome if very large doses are used. The writer has found progesterone in large quantities of benefit in some cases, without any of the disadvantages of the oestrogens. Sedatives, rest, and reassurance have their place.

Safety against Carbon Tetrachloride

Q.—*What safety measures should be recommended for workers using carbon tetrachloride?*

A.—The first essential is adequate general ventilation; the second, a system of mechanical exhaust ventilation over any open vessels containing carbon tetrachloride. Workers with a past history of any liver disturbance, such as jaundice, gall-stones, or infective hepatitis, should not be allowed to handle the substance, nor those receiving arsphenamine treatment, nor pregnant women, nor any worker who has recently had a general anaesthetic such as chloroform. Whenever possible work on carbon tetrachloride should be alternated with periods of work involving no exposure to chlorinated hydrocarbons.

Schistosomiasis

Q.—*Is there any means of determining whether any male schistosomes have survived a course of treatment for bilharzia infection? (Attention has been focused on the escape of ova and treatment usually discontinued when this ceases, though the male parasites predominate.) Can these inescapable worms cause interference with the circulation once they have become dislodged from their favourite sites? Are pathological conditions of the ureter in bilharzia cases due only to microbic invasion spreading up from the bladder wall?*

A.—A quantitative fall and ultimate disappearance of the titre of the complement-fixation test for schistosomiasis would be evidence that the treatment had eradicated the infection. The technique of the test is similar to that of the Wassermann reaction, but an alcoholic extract of the livers of infected snails is used as an antigen. Drugs employed against schistosomes owe their value not only to their effect on the ova but also to the fact that they are lethal to the adult parasites. Their action is far more than one of dislodging the worms, and the death of the adults will result in cure of the disease within the limits of resolution of the concomitant pathological changes of the tissues of the host. Although microbic invasion from the bladder, and other secondary changes, account for a great part of the trouble in the ureter and kidneys in cases of schistosomiasis, specific invasion of the latter tissues may occur and ova have been found in these organs.

Fröhlich's Syndrome

Q.—*What are the modern views on the treatment of Fröhlich's syndrome? Can one, for example, expect benefit from treatment with anterior-pituitary-like hormone, and does the obesity respond to thyroid extract and diet? Exact details of dosage would be welcomed.*

A.—It may be as well to mention that Fröhlich's syndrome is, strictly speaking, a condition of obesity and sexual underdevelopment due to a tumour in the neighbourhood of the pituitary. Surgical treatment should be advised. The term is, however, loosely and inaccurately used to imply obesity and sexual underdevelopment without a tumour. It would seem that obesity in children may delay sexual development, for the treatment of the obesity by diet alone is followed by the attainment of normal sexual development. The obesity may be due to sedentary habits or overfeeding, but there is reason to believe that a functional abnormality of the hypothalamus is often present.

The patients may recover without treatment of any kind, but often a female distribution of fat and body hair persists when obesity and maldevelopment are no longer present. As these are embarrassing symptoms in a man, all patients should be treated in childhood. Diet alone is sufficient. Carbohydrates should be cut drastically, the necessary caloric requirements being made good so far as is possible by proteins. Very little salt should be allowed. Diuretics accelerate loss of weight. Thyroid should be given only when, as sometimes occurs, there is evidence of hypothyroidism. Anterior-pituitary-like hormone of pregnancy urine should be given only when the testicles are undescended—a not uncommon complication. It has no effect upon the obesity, but may accelerate the growth in size of the penis. It is best given only when the time of normal puberty is approaching.

The dose of thyroid is 1/4 grain increased gradually at fortnightly intervals until an increasing resting pulse rate or too rapid a loss of weight suggests that the limit of tolerance is at hand. It should then be omitted for a fortnight, and thereafter continued in a smaller dose. It is rarely necessary to give it at all, and should be given only when careful supervision can be exercised. The dose of A.P.L. hormone is 500 rat units twice weekly intramuscularly in alternate months.

Podophyllin for Warts

Q.—*What is known of the treatment of warts by podophyllin? Please supply references if possible.*

A.—Treatment of warts by podophyllin was described by Culp, O. S., Magid, M. A., and Kaplan, I. W., *J. Urol.*, 1944, **51**, 655; and MacGregor, J. V., *B.M.J.*, 1945, **1**, 593. A 25% suspension in mineral oil or a paste made with podophyllin and water is applied to penile, vulval, or anal warts or warts in other moist sites, for a period of six hours and is then washed off. Occasionally more than one application is necessary. In these sites the warts dry and drop off within a few days. Podophyllin is an irritant, but is rarely an effective measure except for the type of wart found in moist sites.

Prognosis after Splenectomy

Q.—*What advice and prognosis should be given to an otherwise healthy young man who has had a splenectomy owing to rupture as a result of injury?*

A.—Resistance to protozoan infections such as malaria is believed to be reduced by splenectomy. The patient should, therefore, be advised not to visit the Tropics, but apart from this no precautions are needed and the expectation of life and health is normal.

Terminating Pregnancy

Q.—*A married woman is suffering from severe pulmonary tuberculosis and also showing signs of myocardial degeneration. She has become pregnant, and I could have her curetted, but that involves the risk of an anaesthetic. Would it be possible to terminate her pregnancy by means of a glandular preparation—e.g., stilboestrol? If so, what would be the best method of administration and dosage?*

A.—When the foetus is dead but retained *in utero*, stilboestrol and other oestrogens, if given regularly over the course of 5 to 8 days, usually sensitize the uterine musculature to such an extent that expulsion of the products of conception occurs. If, however, as in this case, the pregnancy is alive, oestrogens, even in massive doses, do not produce abortion except on rare occasions when the patient is perhaps unusually sensitive. The same applies to the use of strong purgatives, quinine, ergot preparations, pituitary extracts, etc. Although the possibility of this patient or her uterus being susceptible might make some kind of medical induction worth trying, it is unlikely to be successful, and some form of operative interference will probably be required. The anaesthetic risk would be reduced to a minimum by the employment of a skilled anaesthetist, to whom the choice of anaesthetic should be left. Alternatively, it is possible to carry out dilatation of the cervix and to insert a pack or laminaria tents or even to evacuate the uterus, after infiltration of the cervix and the broad ligaments with a local analgesic. But if the condition of this patient is so grave as to warrant induction of abortion, there is much to be said for sterilization at the same time. In that case there can be little doubt that the ideal treatment would be to carry out abdominal hysterotomy and sterilization under local analgesia—a technique which is not difficult.

INCOME TAX

Expenses: Life Assurance Allowance

J. K. inquires (*a*) whether he can claim as an expense the fee of £5 1s. paid to the General Medical Council for *original* registration, and (*b*) whether the restriction of the life assurance allowance to one-sixth of the income is determined by gross income or gross income less allowable expenses.

⁂ (*a*) The fee in question would appear to be paid in order that the practitioner may exercise his profession rather than incurred in the course of his work. We think that the Revenue authorities might successfully contend that this particular payment was of a capital nature and therefore not allowable. (*b*) The phrase used in the statute is "one-sixth of the total income of the person from all sources estimated in accordance with the provisions of the Income Tax Acts." The earned income must therefore be taken at the assessable amount—i.e., the expenses must be deducted.

Locumtenent

T. L. states that most of his income is derived from work as locumtenent and that he is assessed on his annual earnings and not dealt with under the "pay-as-you-earn" system. Can he claim to deduct the expense of travelling between his residence and the places where he does locumtenent work?

⁂ If, as we gather, the changes in the locumtenencies are sufficiently frequent to justify T. L. in being regarded not as the employee of various practitioners from time to time but as carrying on his profession in a particular manner, then in our view he is assessable under Schedule D and not under Schedule E. If so, he should be regarded as carrying on his profession from his residence as the centre, and the expense of travelling should be allowed.

LETTERS, NOTES, ETC.

Breast-feeding of Infants

Lieut.-Col. W. E. C. **Lunn-Rockliffe**, R.A.M.C.(ret.), writes: In a recently published book, *The Farming Ladder*, by George Henderson, I came across the following passage (page 68): "I once had the pleasure of studying some records kept by a farmer in Northern Ireland over many years, which showed conclusively that for production and longevity the cows which had been reared on two outlying small farms, with ample milk available, had far surpassed those reared under the farmer's own careful supervision on calf meal, where he was in a position to retail every pint of milk produced, and had therefore been misled into believing that calf-rearing with meal was more economical. It is useful in changing over from milk, and we use it, but we still believe that the cow will return a hundredfold the milk she received as a calf, or will withhold in proportion that part of her birthright of which she has been robbed, through the reduction in health and vitality resulting from it. It is not what a calf looks like at six months old that matters, it is how much milk she will be giving at six years old or later." If this is true of cattle may it not also apply to human beings, and explain to a certain extent the difficulty modern mothers appear to have in providing sufficient breast milk for their infants? Possibly their own mothers for some reason denied them their full quota of breast milk; hence the vicious circle.

Fish-bone embedded in Tonsil, Simulating Neoplasm

Mr. A. J. **d'Abreu**, M.B., F.R.C.S.Ed., writes from Newtown, Waterford: In January, 1926, a woman aged 61 consulted me for pain in her throat, shooting up towards her right ear, and slight dysphagia. She gave a history of swallowing a fish-bone a year ago, which she thought had stuck in her throat. She attended hospital in Swansea; no fish-bone was discovered, and she was treated with gargles, making repeated attendances at the hospital. On examination I found that the right tonsil was swollen and projected much beyond the pillars; I could see a slough on it. There was a small gland at the angle of the jaw. The tonsil felt hard on palpation, and yet it was not the hardness of a carcinomatous tonsil. The diagnosis was in doubt. Under regional analgesia the whole tonsil in the lingual prolongation, and the posterior pillar which appeared to be involved, were excised and "hemaplastin" injected around and into the tonsillar fossa. There was no post-operative bleeding, and the throat healed in due course of time with complete disappearance of symptoms. The whole mass was sent to the pathologist, whose report stated that there was no malignancy, that the tonsil was myxomatous, and that in its centre there was a fish-bone.

Bart's in the War

The Treasurer's latest report of St. Bartholomew's Hospital opens with these words: "Although this report is intended primarily to cover the activities of the hospital in 1944, I cannot put off till next year all reference to the vital events of the early part of 1945, culminating in the cessation of hostilities in Europe. For five and a half grim and tragic years our ancient hospital, standing in the heart of the City, battered and shaken by bombs and fire and rockets, has proudly carried on, without a break, its task of succouring the sick, the wounded, and the suffering. Never once during all that time were its doors closed. Often there was no water, no gas, no light. But still the hospital carried on. We are entitled to be proud of our record of over eight centuries of service, but never during its long history has Bart's added more lustre to its name, or earned more affection and regard, than during these years of war. The Governors are deeply conscious of the debt they owe to the medical, nursing, and lay staffs, whose untiring and devoted labours were so wholly in keeping with our ancient traditions and enabled the hospital to retain its record of continuous service unimpaired. We look forward now to brighter times ahead, but they are times which will be fraught with difficulties and problems allowing of no easing up of our efforts."

Disclaimer

Dr. G. **Roche Lynch** (St. Mary's Hospital, Paddington) writes: Please allow me to inform your readers that I was in no way responsible for communicating to a reporter any statement to the effect that Her Majesty the Queen had at any time visited my laboratory. The article which has caused me serious misgivings appeared in the *Daily Express* for Wednesday, Oct. 17, 1945, and was entitled "Just near Paddington Station." Steps have been taken to register a strong protest with the editor of the newspaper concerned, pointing out the erroneous statements that have appeared in the article.

Correction

There was a mistake in the fifth line of paragraph 3 of Major H. L. Thornton's note on "Wide-bore Endotracheal Connexions" (Oct. 20, p. 534). The internal diameter of the distal end is *1.7 cm.* not 7.5.

BRITISH MEDICAL JOURNAL

LONDON SATURDAY NOVEMBER 3 1945

THE AETIOLOGY OF GALL-STONES*

BY

Sir JAMES WALTON, K.C.V.O., M.S., F.R.C.S.

Surgeon to the London Hospital

In spite of an enormous amount of clinical, experimental, and theoretical work the cause and methods of formation of gall-stones, upon which diagnosis and treatment must be based, have been fogged by the fact that all types of stone have been considered together, whereas there are several distinct types.

Cholesterol Stones

A pure cholesterol stone is single, oval in shape, up to 1/2–1 in. in its long diameter, nodular on the surface, semitransparent and waxy in appearance, light yellow in colour, and on section is amorphous in its outer layers but in the centre may show radiating crystals. If pure it is a light yellow (A 5),† but it may be tinted with bile (6). There is a variety which contains a certain amount of calcium, probably in the form of biliverdin or bilirubin calcium (7 B, C). In this case there are usually several stones.

Like all gall-stones the cholesterol stone is more common in women—the proportion being about 2.5 to 1—and some 80% of the women are married and have children. It is known that the function of the gall-bladder is to concentrate the bile to about one-tenth of its volume. There is a condition, generally known as a strawberry gall-bladder, which, on the apices of the papillary folds, shows masses of cholesterol or a lipoid substance (37) that has been believed to be due to the deposition on or the absorption by the mucosa of cholesterol from a supersaturated solution. It is known that the blood cholesterol is increased in pregnancy, and this type of gall-bladder may be found in pregnancy and in eclampsia (38), and may even progress to the stage of forming papillary masses (39) which might separate to produce cholesterol stones.

For these reasons it has been believed by many—and especially by Aschoff and Bacmeister, who claimed that such stones could occur in gall-bladders entirely devoid of any inflammatory change—that these stones were metabolic. This has been accepted, almost without question, by many physicians, who argue that in many women the cholesterol is increased by pregnancy, and later by overeating and lethargy so that they are often over-weight, and that the gall-bladder concentrates the cholesterol and, the bile acids being reduced, the cholesterol is deposited from solution.

Nevertheless I am convinced that these arguments are fallacious. Sight is lost of the fact that the common age for gall-stones in women is 40 to 60, and of the total female population of this age, whether suffering from gall-stones or not, some 80% are married with children. Stones are rarely formed in the ducts, but when they are they consist of bile pigment and not of cholesterol, as they should be if deposited from a supersaturated solution, and this is true even in cases of obstruction of the duct by carcinoma of the pancreas or chronic pancreatitis. In such cases the bile is concentrated to a profound degree, so that it forms a tarry fluid which may be opaque to *x* rays, but pure cholesterol stones are then never found even in the gall-bladder. They are formed in the gall-bladder either when it is entirely cut off from the bile stream by the stone obstructing the duct (16) or in the distal cavity of an hour-glass gall-bladder (18). No bile is present, and therefore the stones cannot be deposited from a supersaturated bile. They are never laid down as a primary crystalline mass, as they should be if deposited from a supersaturated solution, but are amorphous, although they may undergo secondary crystalline changes in the centre. They are completely insoluble in ether or olive oil although cholesterol crystals are freely soluble in such, but if they are finely crushed so that the organic matrix is broken up they become soluble. Therefore attempts which are sometimes made to remove small stones from the ducts by washing them out with ether are based on incorrect knowledge and are ineffective. In my own experience every cholesterol stone has been associated with cholecystitis, in some cases purulent (4). Therefore these stones are certainly not metabolic, but are formed by an inflamed gall-bladder.

Pigment Stones

Pure biliverdin calculi form small irregular friable masses of so dark a green that they are nearly black (9). They may be formed in the ducts or be found in the gall-bladder, and in the latter case may become coated with cholesterol (10); but this never happens in the ducts. The pure bilirubin stones are soft putty-like masses of a dark-brown colour. They may be found in relatively large cylindrical masses in the common duct in cases of cholangitis. If a mixed stone has passed down and become impacted in the common duct it may become covered with a layer of bilirubin, but the presence of a laminated centre will be proof that it originated in the gall-bladder. If such a stone is found after a cholecystectomy it must have been overlooked at the first operation, for a newly formed stone would consist of pigment throughout. They may also occur in the intrahepatic ducts, and are often deposited when there is a long-continued obstruction of the ducts and greatly concentrated bile. Like the biliverdin variety they may, if present in the gall-bladder, be coated with cholesterol (12 D). It is the pigment calculi which are found with extensive blood destruction—e.g., acholuric jaundice, malaria, etc. They are easily soluble and therefore often stain the mounting fluid. After removal of the cause they may become absorbed, even if in part covered with cholesterol in the gall-bladder, but in this case the pigment is alone dissolved and the cholesterol is untouched (22). They are therefore certainly metabolic in origin and due to deposition from a supersaturated solution.

Mixed Stones

These are often known as common gall-stones and they may be single or multiple. In the former case they may fill the gall-bladder and are oval in shape, with a surface that is nodular or mammillated from the impression of the mucosal folds (H). If the stone be large enough to obstruct the duct the portion in the duct will remain pigmented, but the greater mass in the gall-bladder will become coated with cholesterol and resemble a pure cholesterol calculus (16, 17). It is this large single stone which is most prone to ulcerate through the fundus into the duodenum, where it becomes coated with intestinal contents and may cause acute intestinal obstruction. If multiple they may be few and large (15), often then forming a chain of barrel-shaped stones filling the gall-bladder, or multiple even up to several hundreds, and may be loose or so numerous that they form a tight mosaic filling the gall-bladder (44). When multiple they are nearly always faceted, either because they fit into one another as they increase in size or because they rub upon each other. They may be stained with biliverdin (E) or bilirubin (F), but in any one case the stones are all of one colour, although Bland-Sutton stated that the bile in herbivorous animals was red and in carnivorous animals green, and suggested that the colour might be dependent upon the diet. If few in number they are often of the same size, and it has therefore been suggested that they are all formed at one time (Rous) or that they may be grouped into several sizes and thus might be formed at a few critical periods (Lichtman); but in my experience they are most commonly of all sizes and might therefore be constantly forming. In my opinion there is little or no evidence that they are formed as the result of one transient episode.

---

* Presidential Address to the Medical Society of London, delivered on Oct. 8, 1945.

† The numbers in parenthesis refer to the List of Specimens given at the end of the paper.

One of their most marked characteristics is that they are laminated on section. In the centre the laminae may consist of radiating crystals, but the external layers are always amorphous. The different laminae may vary in colour but are usually alike. Like pure cholesterol stones they are insoluble in ether or olive oil unless crushed, and they have an organic matrix.

It is on the method of formation of these calculi that there has been so much controversy, the following views being held:

(a) Stagnation of Bile

This was one of the earliest theories of the cause of gall-stones (Galen, Frerichs, Rokitansky, Aschoff and Bacmeister, etc.), and is still supported in many recent monographs and textbooks of medicine. It is believed that stasis without infection could lead to the precipitation of bile salts and cholesterol—a view that was considerably strengthened by the knowledge that in the gall-bladder the bile was concentrated to one-tenth of its volume. Stasis was believed to be more common in women because they wore corsets (but gall-stones have not become less frequent since tight lacing has been abandoned); because of the pressure from the pregnant uterus and later from the development of ptosis (but although the symptoms of ptosis may resemble those of gall-stones the two conditions are rarely found together); and because of their sedentary habits. Gall-stones, however, may be found in thin and active people. The supporters of this view have even blamed the wearing of a belt in men as a cause, but in most men the position of a belt has no relation to the position of the gall-bladder. The main argument against stasis being a causative factor is that this type of stone never occurs in conditions of profound stasis such as obstruction of the common duct—that, in fact, they are never formed in the ducts at all, and are not deposited as crystals, but are always amorphous, with an organic basis, and therefore are insoluble in ether and olive oil. As Robertson says: "Stasis, so useful in the laboratory test-tube experiment, is not the cause of gall-stones." Newman is more emphatic when he states that "stasis in itself is no explanation for anything."

(b) Metabolic Changes

In 1789 de Fourcroy discovered cholesterol and showed that it was a constituent of gall-stones. Since then many observers have claimed that cholesterol is increased in the blood during pregnancy, but it is not evident that this affected the cholesterol content of the bile. It was later shown that the removal of bile salts from the bile led to precipitation of the cholesterol, and Thudichum believed that fermentation of the bile caused a splitting of the bile acids and alkalis and so led to a precipitation of the cholesterol. The same arguments are as true here as in the case of pure cholesterol stones. They are never formed in the ducts, however concentrated the bile; they are never deposited as crystals; but, later, radiating crystals may be formed in the centre, and they are insoluble. It seems certain, therefore, that they are not due to deposition owing to metabolic changes.

(c) Constitutional Susceptibility

Several cases in my own practice have had a *family history*. In particular one girl of 18 whose bladder was full of stones had eight immediate relatives, including both parents and two grandparents, who had had gall-stones; but such a history is unusual. Stress has been laid upon the presence of a hereditary physical constitution (Draper), but most observers (Chauffard, Howard, Tucker, Bauer) have failed to obtain evidence in support of his conclusions. Even if a family history is obtained it is always possible, as in other diseases, that it might be due to a similar environment.

Association with Urinary Calculi.—The association of the two conditions has been believed in from very early times, but Robertson could find no evidence to support it, and states that the number of patients who harbour both types of stone has not proved large enough to justify the belief. Nevertheless in a series of cases I investigated and reported over 30 years ago 80% of the patients with gall-stones had *B. coli* in their urine.

Association with Diabetes.—Many statistics have been published in support of the view that biliary calculi and diabetes were frequently associated. Bouchard found gall-stones in 10% of diabetics, and Jones places the incidence as high as 22%; but Naunyn and Kausch state that the combination is uncommon. Robertson in his masterly review‡ reports the results of 4,761 necropsies in patients over 20; 3,016 were males and 1,745 females. Gall-stones were present in 22% (500 men and 532 women). Diabetes was present in 205 of the total of 4,761. Of these, 76 (37%) had gall-stones, while of the 4,556 non-diabetics 956 (21%) had gall-stones. It is very probable, however, that the gall-stones have given rise to a pancreatitis and so caused the diabetes; for, as Robertson says, in nearly all cases the symptoms of gall-stones precede those of diabetes, and diabetes is not the cause of gall-stones.

Excessive Weight.—There is a general belief that gall-stones are more common in fat women, and that idleness, lethargy, and overeating are the cause of increased cholesterol formation and the development of gall-stones. The experience at my own hospital supports the view that they are more common in fat Jewesses. Nevertheless it has been shown that there is very little evidence that increase of cholesterol in the blood is the cause of cholelithiasis, and stones often occur in thin people. Although Dublin, Gross, and Joslin, among others, have produced statistical evidence that sufferers from gall-stones are usually over weight, Robertson found in his 1,032 cases with gall-stones that 578 (56%) were of normal or subnormal weight. Even if they are more common in fat patients, there is no more evidence that the fat caused the gall-stones than that the stones caused the fat.

Other Diseases.—Arteriosclerosis, gout, and tuberculosis have all been described as predisposing causes, but there is no evidence of any such relationship.

(d) Neurogenic Dysfunction

In recent years, when so much stress has been laid upon the nervous basis of disease, it is but natural that a neurogenic origin should be suggested for gall-stones. Westphal has perhaps been the strongest supporter of this view: he was able to demonstrate contractions of the gall-bladder with expulsion of the bile after mild irritation of the vagus, and relaxation with dilatation of the gall-bladder after stimulation of the splanchnic or sympathetic nerves. He and others claimed that in pregnancy a distension of this type occurred. This is, however, merely a variant of the theory of stasis, and the proof that such a dilatation, if present, is the cause of gall-stones is entirely wanting.

(e) Infection

The three main arguments against stasis and the metabolic origin of these and of pure cholesterol stones are that cholesterol is never laid down in the ducts; that it is deposited in the amorphous and never in the crystalline state; and that the stones are insoluble. Naunyn first asserted that cholesterol was not derived from the bile but was secreted by the epithelial cells of the gall-bladder and that cholesterosis of the bladder was similarly due to this secretion and not to absorption from the bile. He also showed that the newly deposited material was amorphous and not crystalline, and that there was always evidence of inflammation of the gall-bladder. Later he claimed that the *B. coli* was always present. Mignot pointed out that the infection was always chronic, and this indeed was to be expected, for in an acute infection of short duration, as revealed by operation or at necropsy, no stone would have had time to be formed.

It is of interest to note that even Hippocrates and Galen recognized the possibility of an organic basis, but it was not until 1684 that v. Heyde was able to extract the crystalline material from a urinary calculus and leave an organic basis. Ord laid stress upon the presence of a colloid, and Wells described what is now a well-recognized physical phenomenon—that crystalloids concentrate around the globules of a colloid, a process known as adsorption. There was at first a difficulty in accepting this explanation; for the colloid was believed to be mucus, but many failed to find it in the mucosa of the gall-bladder. Later Policard showed that the inflamed cells could take over the function of producing mucus. Many, however, regarded it simply as a binding or cement; but whereas the physical process of adsorption—where the crystalloid is deposited upon the surface of the globules of an irreversible colloid, probably owing to changes in surface tension—gives a ready explanation of the insolubility of a gall-stone in solvents of cholesterol, the mere presence of a cement does not.

Many have believed (Herxheimer, Collinson, etc.) that the presence of a nucleus was of prime importance, as there is a tendency for both colloids and crystalloids to precipitate around a central core. The nucleus is believed to be formed of clumps of bacteria, which were first demonstrated by Gallippe, epithelial cells, or duct concretions. Moynihan's statement that every gall-stone is the tombstone of a dead bacterium has now become classical. Some have raised the objection that experimental or critical investigations have failed to demonstrate a nucleus, but the occasional presence of a silk suture (57) or a dead intestinal worm is a nucleus that is plain for all to see. It must be clearly understood that there is not a simple deposition of crystals around the nucleus but a process of adsorption.

---

‡ *The Preponderance of Gallstones in Women.* H. E. Robertson. *Int. Abs. Surg.*, **80**, No. 1, Jan., 1945, p. 1.

The nature of the infection that leads to the secretion of mucin and cholesterol is probably very variable. When typhoid fever was endemic acute cholecystitis was common, and every surgeon is conversant with cases where gall-stones have followed typhoid. The patient is a typhoid carrier with *B. typhosus* in the stools, and after removal of the inflamed gall-bladder and stones (43) no more bacilli are passed and he ceases to be infectious. Although many writers have refused to accept the view of infection there can be no doubt that it is present in such cases. Hanot, and later Deaver, laid much stress upon the presence of the *B. typhosus*. Welsh has shown that coccal infections may act in a similar manner, and the work of Gordon-Taylor and Whitby demonstrating the presence of *B. coli* is known to you all. The greater liability of women to a systemic *B. coli* infection, especially during pregnancy, may account for their increased tendency to develop gall-stones.

Another factor upon which discussion has centred is the laminated structure of these stones. Many have compared them with other animal concretions, such as pearls, which have a similar organic matrix, or with mineral materials such as agates (1), or even with the world itself, and have regarded them as examples of the universal tendency in nature for the formation of alternating deposits of a different character; but the pure cholesterol stone does not show such lamination. The simple explanation, however, would seem to be that at times the stone obstructs the cystic duct so that pure cholesterol secreted by the bladder-wall can alone be laid down, while at other times the duct is free, bile can enter, and layers containing pigment are formed.

It would appear, therefore, to be beyond question that the stones are inflammatory in origin. Reacting to infection, the gall-bladder secretes the colloid mucin and the crystalloid cholesterol; a nucleus is formed of bacteria, epithelial cells, or, rarely, of a foreign body. If there be but one nucleus the stone is single, if multiple there are many stones. The crystalloid is deposited upon the colloid globules in an amorphous form by a process of adsorption, but later undergoes a secondary crystallization. If the cystic duct is permanently obstructed a pure cholesterol stone is formed (J), but if the obstruction is intermittent it is laminated. If the stones are multiple they are faceted either as they fit into one another as they are formed or by friction one against another. As the colloid is irreversible they cannot be dissolved or dispersed by any method of treatment.

Paths of Infection.—The next question that has given rise to controversy is the manner by which the infection reaches the gall-bladder. It was at first natural to assume that it passed up the duct from the intestine. Every surgeon, however, is aware of the fact that in the majority of cases of either acute or chronic cholecystitis the duct shows no sign of infection, and that when an infection is present a stone, laminated like those in the gall-bladder from the presence of cholesterol and which must therefore have been formed in the gall-bladder, is found in the duct. If its presence in the duct has caused a cholangitis a new layer is formed on the stone, but this always consists of pure bile pigment and never contains cholesterol. Moreover, there is an increasing volume of evidence that infection of any organ of the body—stomach, kidney, bladder, pancreas, etc.—rarely enters by the natural path or duct. It would seem that the protection against infection by this path is so efficient that it seldom breaks down. Moreover, stones rarely form when there is a partial obstruction and stasis in the duct such as occurs with carcinoma or chronic pancreatitis. This freedom of infection of the duct is evident from the fact that nearly all patients with gall-stones are completely cured by cholecystectomy.

The view that organisms might be absorbed from the intestinal wall into the portal vein and be excreted in the bile was attractive, for such organisms would very likely have an attenuated virulence and thus would more probably cause a chronic cholecystitis; but here again an infection of the ducts, the liver, and the portal vein would be evident, but it is generally absent.

A certain amount of evidence has been produced that the infection may spread directly or by means of the lymphatics from the liver, and Graham has pointed out that in nearly all cases there is some fibrosis of the adjacent liver; but it would appear more probable that the inflammatory change has spread from the gall-bladder, for it is limited to the area in close proximity to the gall-bladder and is never widespread in the liver.

Many investigators have been struck by the fact that in the presence of gall-stones the bile was often sterile. At first it was believed that the organisms, having initiated the formation of the stones, had died out and were present, either alive or dead, only in the centre of the stones. Since then much work has been done showing that even if the bile is sterile organisms can be obtained from the gall-bladder wall. It is necessary to refer only to that of Illingworth and Wilkie, who obtained streptococci in this position, and of Gordon-Taylor and Whitby, who isolated the *B. coli.* The experimental work of Mann showing that the injection of formalin into the lateral ear vein of a rabbit was shortly followed by an acute cholecystitis seemed to prove that an infection could also take place through the systemic circulation. The claims of Rosenow, that his work demonstrated so marked a specificity of organisms that those removed from an infected gall-bladder and injected into the peripheral blood stream of an animal would in the majority of cases produce a cholecystitis, were attractive from this point of view. Many pathological specimens would support this idea. Specimen 43 is an example of a typhoid cholecystitis from a typhoid carrier in which there is gross fibrosis of the wall but only small calculi, suggesting that the primary infection must have been in the gall-bladder wall. Specimens of intramural calculi where the stones are in the mucosal crypts in the wall but none are present in the cavity (40, 40a, 40b), and of calculus formation around a silk suture in the fundus of the gall-bladder, are very suggestive (57).

One is therefore led to the conclusion that not only are these stones due to an infection, but this infection is carried to the gall-bladder wall through the systemic circulation.

Calcium Carbonate Stones

The most interesting stones, and the kind most difficult of explanation, are those formed of pure calcium carbonate. In the fascinating book *Gall-stones,* written by the late Sir John Bland-Sutton in the early years of this century, the author states that he knew of only two such cases, but since then I have been able to collect five from my own practice, which are now in the museum of the London Hospital. They may occur in two forms, one of which consists of well-formed extremely hard calculi that are spherical, with a nodular surface. They are generally small and relatively few in number (19), but in one remarkable specimen (20) there were 11 stones in the gall-bladder and 28 in the common duct. The yellowish-white colour and the nodular appearance give them a close resemblance to pigment stones which have become covered with cholesterol in the gall-bladder. In fact, in the specimen I so mistook them until I attempted to cut one to demonstrate the pigment centre and broke a piece out of the knife. The other variety consists not of a formed stone but of a thick white paste resembling unset plaster-of-Paris, which may fill the gall-bladder (21) and have embedded in it one or two mixed gall-stones. Specimen 21a is an example. The pure calcium carbonate gives, of course, a deep *x*-ray shadow, and in this case the cavity of the gall-bladder was well outlined as though dye had been administered, with two negative shadows due to the stones. When it was known that no dye had been given the diagnosis was certain.

The reason for the formation of these rare stones is very difficult to understand. Elsewhere in the body the deposition of calcium carbonate is indicative of a very slow and chronic inflammation of connective tissue, and hence it would be expected that the gall-bladder would show a very chronic change, with destruction of the mucosa; but although this is true of calcification of the gall-bladder wall it is not the case with calcium carbonate stones. In one specimen (24) a typical deposit of soft material was formed in a case of alcholuric jaundice where pure pigment stones would have been expected. In none of my cases was there any evidence of hyperparathyroidism. At present I must confess that I have no explanation to offer for this unusual phenomenon.

Conclusion

I trust that I have been able to show that there is still much of interest to be learnt from the everyday experiences of surgery, and that to those of a curious and inquiring mind there are still big fields of research in the observations of gross pathology.

LIST OF SPECIMENS REFERRED TO IN THE TEXT

A 5. Pure cholesterol stones.
6. Pigmented cholesterol stone.
7, B, C. „ „ „ with calcium carbonate.
37. Strawberry gall-bladder.
38. „ „ „ in eclampsia.
39. „ „ „ , with papillary masses.
16, 17. Cholesterol covering stones, with obstructed duct.
18. Cholesterol covering stones in distal pouch of hour-glass gall-bladder.

4. Cholesterol stone associated with acute purulent cholecystitis.
9. Pure biliverdin stones.
10. „ „ „ coated with cholesterol.
12, D. Bilirubin stones coated with cholesterol.
22. Partly absorbed stones.
H. Large single stone in gall-bladder.
15. Barrel-shaped stones.
44. Mosaic of gall-stones in gall-bladder.
E. Multiple-faceted biliverdin stones.
F. „ „ bilirubin „
43. Typhoid cholecystitis.
1. Agate showing lamination.
J. Laminated stone covered with cholesterol.
40, 40a, 40b. Intramural calculi.
57. Recurrent stones formed round silk sutures.
19. Small calcium carbonate stones.
20. Large „ „ „
21. Putty-like mass of calcium carbonate.
21a. „ „ „ „ „ „ with common stones.
24. „ „ „ „ „ „ from case of acholuric jaundice.

ON "ACROPARAESTHESIA" AND SO-CALLED "NEURITIS" OF THE HANDS AND ARMS IN WOMEN

THEIR PROBABLE RELATION TO BRACHIAL PLEXUS PRESSURE BY NORMAL FIRST RIBS

BY

F. M. R. WALSHE, M.D., D.Sc., F.R.C.P.

During the past four years I have seen an unusual number of cases in which the presenting symptoms have been numbness, tingling, and "uselessness" of the hands and fingers in women, often associated with severe pain and a variable degree of disability. By the time such patients reach the neurologist they have usually been given prolonged, various, and largely ineffective treatments. It is improbable that my experience in this matter is unique, but since there is clearly general uncertainty as to the aetiology and nature of the condition and as to the means of dealing with it effectively, a short account and some suggestions as to its causation may not be amiss.

I have said that the patients are women, but the incidence of the syndrome may be still further restricted. The sufferers fall into two main categories. The most numerous are middle-aged or elderly women, normally unaccustomed to full housework or other forms of manual effort, who, under wartime circumstances, have been obliged to undertake the entire work of their homes with all that this involves in the preparing of food and meals, cleaning, shopping, standing in queues, and the carrying of heavy shopping baskets. The second category is composed of younger women who, in addition to the not light tasks enumerated, have also done part-time work in industry, or have had the burden of childbirth and the care of young children.

In both categories the history has the following characteristic features. The symptoms have been gradual in onset and consist of intense sensations of numbness and tingling in hands and digits. These are greatest on waking in the morning, when they make the fingers clumsy and weak. By the time the patient has dressed, the symptoms have lessened and hands and fingers regain much of their dexterity. Nevertheless, they remain uncomfortable and less than normally nimble all day, and in the evening, when the major burden of the day's work is over, the symptoms increase again. During the night pain and paraesthesiae in the fingers may awake the patient, the pain being of a burning character. The subject may have to adopt various measures to secure relief: getting up and walking about, putting the arms over the edge of the bed, or placing them upon the pillow above her head. In yet other instances the night is the period of relief. An unusually hard day's work aggravates the symptoms, while such tasks as ironing, washing, and the carrying of heavy baskets are especially provocative of severe accesses of pain and numbness.

After some weeks or months the symptom-complex reaches its maximum, and thereafter fluctuates in severity and disabling quality from patient to patient. It varies also from time to time according to the patient's general health and state of fatigue. Pregnancy and the care of the child after confinement undoubtedly aggravate the condition.

The response to the treatments commonly adopted is uniformly disappointing, for whatever the mode of therapy the patient is commonly expected to remain ambulant and to follow her normal routine of life. The sage maxims of Hilton in the matter of rest are forgotten, and find an ineffective substitute in injections of vitamin B_1, the oral administration of vitamin combinations, and diverse forms of physiotherapy. The patient is treated by what is thought to be science, and certainly not by anything that can be called the art of medicine. In middle-aged women, of course, the oestrogens are invoked with no fruit, and when the desperate patient has sought relief from practitioners not on the *Medical Register* "manipulation of the spine" has still further added to her torments.

A few of the sufferers have discovered for themselves that a rest or holiday affords remarkable relief, but the fact provides a clue that no one is interested to follow to its logical conclusion—namely, that it suggests a mechanical origin of the syndrome.

On examination the subject is commonly found to show the general indications of chronic fatigue, and indeed the sense of fatigue may be one of her bitterest complaints. The musculature is atonic; often the shoulder girdles are set notably low, so that the line of the clavicle as this is followed out from the sternal end is almost if not quite horizontal. It is known that this state of affairs—a progressive lowering of the shoulder girdle—is the rule in women as middle age is reached and passed, and it is therefore not always clear that this sagging is beyond the limits of the normal; but my own impression is that this is commonly so in these cases. In a proportion of them traction on the dependent arm obliterates the radial pulse, though this is not constant, and may indeed be found in persons who are symptomless.

There is no muscular wasting, but almost always marked tenderness of the extensor muscles in the forearm, and sometimes of the thenar and adductor muscles of the thumb. Objective sensory loss is exceptional, though when pain and paraesthesiae are maximal there may be some blunting of cutaneous sensibility over the digits. Cyanosis or pallor of the fingers is occasional, but Raynaud's syndrome is no essential part of the picture. The pain and discomfort and the muscle tenderness may lead to some apparent weakness of grasp and to notable clumsiness of finger movements. Radiography reveals no abnormality except the lowering of the outer end of the clavicle already alluded to, but of course an occasional case of cervical rib is revealed in this way.

In brief, the condition is one in which subjective symptoms predominate or exist alone and objective signs are scanty.

The syndrome is not unfamiliar to clinicians, but what is new is its widespread incidence. Formerly confined to women habitually doing heavy work, such as washerwomen, it is now found throughout the social scale. One other point may be made at this juncture, in anticipation of what is to be said of treatment—namely, that the symptoms characteristically respond to rest, but not to any other modes of treatment unless rest accompanies them, when it may be suggested that they are superfluous and inoperative.

Aetiology

The condition thus briefly described is the one familiar to us under the uninformative title of "acroparaesthesia." In textbooks of medicine it finds cursory mention among vascular diseases and is described as a vasomotor neurosis—a meaningless term that is nowhere defined, and one for the use of which no reasons are offered. Authors stress the absence of objective signs, and agree that it is bilateral and common in middle-aged women, in debilitated subjects, and—by way of a parting shot—in those who are emotionally unstable.

Treatment is generally allowed to be unsatisfactory, and includes radiant heat, massage, ionization, diathermy, thyroid extract, calcium of course, bromides, salicylates, and vitamins. Not one of these remedies but has been described as useless by some writers, valuable by others. No one can doubt that the syndrome will shortly be conscripted into the swelling ranks of so-called psychosomatic disorders, from which it will with difficulty be rescued for medicine proper.

It is now often diagnosed as polyneuritis or, when it is seen in or immediately after pregnancy, as the polyneuritis of pregnancy, and it is in these circumstances made the subject of recondite speculations as to the metabolic disorders and vitamin deficiencies of this state. It may be doubted whether polyneuritis is in question at all. Multiple symmetrical peripheral neuritis, to give it its full name, has certain constant objective signs which include paresis, loss of tendon-jerks, sensory loss, and a distribution involving all four limbs, the lower limbs being the most severely affected. We know nothing of a polyneuritis affecting the upper limbs alone and unaccompanied by the objective signs enumerated. In short, the syndrome of acroparaesthesia does not come in this category at all and cannot rightly be labelled "polyneuritis."

When we not only survey the signs and symptoms of acroparaesthesia but consider also the factors of general health which accompany its appearance, we find that the factors common to all cases are fatigue and debility and the heavy use of the arms and hands. There is no evidence that pregnancy *per se*—that is, as a state associated with metabolic or toxaemic disorders—is a causative factor, but like debility and asthenia it is an added physical burden to an already overworked woman. In short, the incidence of acroparaesthesia among women may be related to a simpler and less speculative factor than these; namely, to an anatomical factor—the topographical relation of shoulder girdle to upper thoracic outlet.

In a recent paper on rib-pressure syndromes in association with cervical, rudimentary, and normal first thoracic ribs (Walshe, Harvey Jackson, and Wyburn-Mason, 1945) the authors make a passing reference to the syndrome which is the subject of the present paper and suggest that this also is a rib-pressure syndrome, the rib in this case being a normal first rib. Rib-pressure syndromes fall into two categories: those in which the upper thoracic outlet is abnormal from the presence of a rudimentary seventh cervical or first thoracic rib, and those in which the operative factor is an altered relationship between the shoulder girdle and a normal upper thoracic outlet. This last is the category now in question.

The components of all rib-pressure syndromes are nervous and vascular, and in the individual case either or both may be present. Reasons are given in the paper referred to for thinking that the vascular symptoms are invariably due to interference with the flow of blood through the subclavian artery, either as it crosses the edge of the thoracic outlet or by compression in certain positions of the arm between clavicle and thoracic outlet. The nervous symptoms are similarly caused; and here also, contrary to what has been commonly believed, the elements of the brachial plexus involved may be caught between the arms of the vice formed by clavicle and rim of the thoracic outlet. Costo-clavicular compression of the subclavian artery and vein has been fully discussed in an earlier paper by Falconer and Weddell (1943), but these authors did not consider whether nervous structures might also be affected in this way.

It is not germane to the purpose of this paper to describe the major symptoms that may ensue in cases of normal first-rib pressure. These are fully discussed in the paper by the three authors already referred to. What is here submitted is that traction and compression of the lower trunk of the brachial plexus and possibly also of the subclavian artery are the essential mechanical factors underlying most, if perhaps not all, cases of acroparaesthesia in women, that these factors are caused by sagging of the shoulder girdle, and this, in turn, is a natural consequence of an atonic supporting musculature. In the group of cases under consideration the traction and compression are minimal, capable of producing pain, tingling, and numbness, and at times some cyanosis of the digits with coldness, but not adequate to produce the graver nervous or vascular disorders. Whereas rib-pressure syndromes due to an abnormal upper thoracic outlet (rudimentary cervical or first thoracic rib) are usually unilateral, because the thoracic outlet in these cases is commonly asymmetrical, the minor normal first-rib-pressure syndromes are bilateral, because here the thoracic outlet is symmetrical and the sagging of the shoulder girdles—being dependent upon a general muscular atonia—is also bilateral. If the symptoms are more marked on one side this is commonly the right, the right hand and arm being the more constantly and heavily used.

We have, in short, a simple mechanical factor capable of producing the characteristic syndrome of acroparaesthesia, and corresponding in its incidence to the clinical group in which the syndrome is found—namely, the debilitated, atonic, and fatigued woman, either middle-aged or recently recovering from illness or childbirth.

The temptation to find a single pathology for a well-defined clinical syndrome is a strong one, and may often be fallacious, as we have recently seen in the sweeping and unsubstantiated doctrine that all cases of sciatica are due to herniated intervertebral disks. Nevertheless we may regard the mechanical factors that have been described here as probably accounting for the great majority of cases of acroparaesthesia in women, and as factors to be excluded before more recondite and speculative aetiologies, metabolic and dietary, are invoked. It should be added that this view of the aetiology of acroparaesthesia has been expressed by other writers in the past, notably by Wartenberg (1936, 1944), and is therefore not here advanced as original, but rather because current modes of treatment show it to be generally unfamiliar to clinicians. The remedy proposed by Wartenberg, however—namely, division of scalenus anterior—is not recommended, as being unnecessary and, when performed, usually fruitless.

Treatment

If, as has been postulated, we are dealing with a mechanically produced "neuritis" of components of the brachial plexus, sometimes with an associated minimal interference with the blood supply to the upper limb, it might be expected that rest—either rest in bed or the simple cessation of manual work—would produce appreciable relief and final disappearance of symptoms. That this does in fact occur is the submission of this paper. It is further submitted that rest is the only effective treatment. The majority of the numerous patients who have come under my own observation have, as already stated, been given prolonged and sometimes heavy dosage with synthetic vitamin B_1, as well as various forms of physiotherapy. When these procedures have not been accompanied by rest they have, in my experience, proved futile, and this also is what might be anticipated if the view as to aetiology taken here is the correct one.

No one is better aware than I that to advise rest from routine housework may often be an impracticable counsel of perfection. Nevertheless if this be the essence of treatment it is important that we should realize it. We have to face the reality of the situation and to avoid putting ourselves in a false position by advising measures of treatment that are invariably ineffective; and that they are so the accounts of acroparaesthesia in the textbooks, as well as personal experience, must have convinced most of us.

In the most severe cases, therefore, an initial period of a week in bed, propped up during the day, with the arms in slings and taken out only for feeding and other necessary purposes, is the most rapidly effective way of securing relief from pain; thereafter a longer period of abstention from heavy housework, and the supporting of the arms in slings whenever possible while the patient is standing or walking. During this second period massage to the shoulder girdles and general tonic treatment tend to prevent recurrence. Analgesics also have their uses in some cases as an adjuvant. If these things can be achieved, other modes of treatment have no value. To ply these unfortunate women with vitamin B_1 is as irrational as to sacrifice a goat to Aesculapius or to send them forth upon a healing pilgrimage to Epidauros.

Summary

The common and well-defined syndrome that goes by the name of acroparaesthesia and is recognized as peculiar to women patients engaged in manual work, when they are debilitated or fatigued, and usually when they are in middle age, is considered as a manifestation of a rib-pressure syndrome. The rib in question is the normal first rib, and traction and compression are exerted on the lower components of the brachial plexus, and sometimes also upon the subclavian artery, when from muscular atonia the muscles supporting the shoulder girdles allow these to droop and sit at an abnormally low level. In short, acroparaesthesia is a mechanically produced syndrome. There is no evidence available for regarding it as dependent upon abnormalities of metabolism—either toxaemic or due to dietary deficiency—or as standing in any specific relation to pregnancy *per se*.

The essential treatment is rest for the limbs. No other treatment is essential, or useful when given without rest. If there be other causes of this familiar syndrome their operation has not so far been demonstrated.

MISSED CASES OF INFECTIVE HEPATITIS*

EVIDENCE OF LIVER DAMAGE WITHOUT SYMPTOMS AMONG A COMMUNITY AT RISK

BY

M. R. POLLOCK, M.B., B.Ch.

There is a widespread conviction that many cases of infective hepatitis fail to be recognized either because jaundice never develops or because symptoms are so slight that the patient does not seek medical advice. Cases with typical symptoms and abnormal liver function tests but no jaundice are well known to occur, although there is difference of opinion as to their frequency. This problem has been discussed in a separate paper (Pollock, 1945). In many of these so-called "subicteric" cases—particularly among children, in whom the disease is known to be generally milder than in adults—symptoms are minimal; and even in cases that do develop jaundice there are reports of this being the first or only symptom of the attack. Where jaundice occurs the case will not often be missed, whether other symptoms develop or not, but if by any chance it were possible for infection to occur in the absence both of jaundice and of subjective symptoms, the case would almost certainly be missed even under close medical supervision. Such persons would fall into the category of subclinical "ambulant cases" and, although themselves suffering no inconvenience, might be just as capable of transmitting the disease as a fully developed case. Ideally they would be detected by isolation of the infective agent or by specific serological tests; but unfortunately this is not yet practicable. If, however, subclinical infection were associated with some degree of liver damage it might be possible, by the use of a sensitive test of liver function, to obtain suggestive evidence by investigating a section of a community exposed to risk. Hallgren (1943) has reported raised serum bilirubin values among contacts during an epidemic in a sanatorium, but in view of the wide individual variation known to occur in serum bilirubin concentration it is uncertain how much significance should be attached to his results. In any case, the possibility of liver damage occurring in the absence of symptoms was considered of sufficient epidemiological importance to merit the present investigation.

Methods

For the continued investigation of large numbers of contacts during an epidemic it was necessary to choose a simple liver function test which could be rapidly performed and easily repeated. For this purpose the detection of small quantities of bilirubin in urine by the sensitive method described by Hunter (1930) was considered most suitable. Work (Pollock, 1945; Gellis and Stokes, 1945) on the pre-icteric stage has shown that bilirubin appears in the urine early in the disease, before the serum bilirubin starts to rise, and the test had been found consistently negative in a large series of healthy persons.

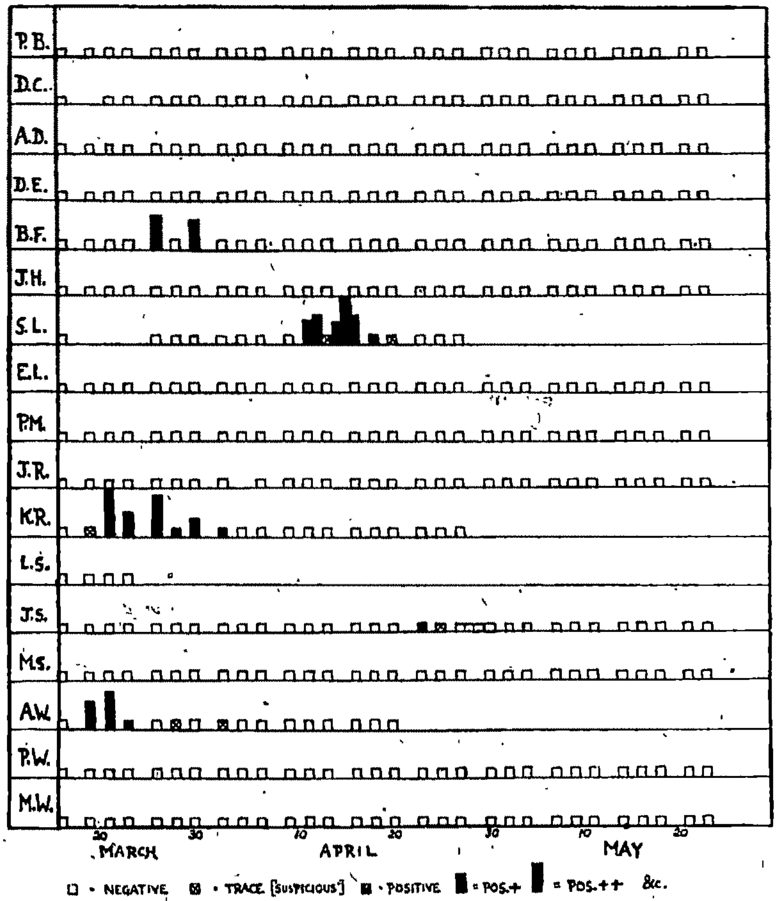

FIG. 1.—Nursery A. Serial Hunter's tests for bilirubinuria in child contacts of infective hepatitis.

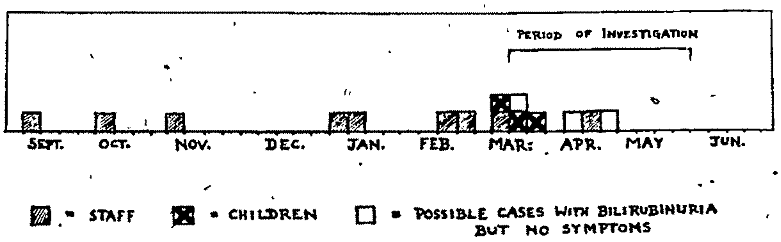

FIG. 2.—Weekly incidence of cases of infective hepatitis in Nursery A.

The technique of the test and method of collection of samples were slightly modified (Pollock, 1945) in order to increase the sensitivity and allow specimens to be kept for 2 to 3 days before analysis without undergoing deterioration.

Results

A good opportunity for testing contacts occurred at the beginning of 1945 in a residential nursery (Nursery A) for children from 2 to 5 years old. Cases of infective hepatitis had been occurring singly or in pairs among members of the staff at approximately monthly intervals since September of the previous year. The place was excellently run and the standard of hygiene and nursing was high. There was a fairly large turnover of staff, both domestic helps and student nurses, but the population of children (total about 35) remained fairly constant. There was little direct contact between children and the outside population, apart from occasional visits of parents.

On March 11 one of the children (P.H.) became ill and developed jaundice 6 days later. This was the first known case among the children, and it was decided that this would be the most suitable time to begin a mass investigation of contacts. Accordingly, arrangements were made for the collection of early-morning samples of urine thrice weekly from 17 children (chosen solely on account of their reliability in providing specimens). The investigation went on continuously for 10 weeks, although by this time 4 of the children had left.

---

* A report to the Medical Research Council.

All but 2 were tested for at least 6 weeks. The results are summarized in Fig. 1. It can be seen that altogether 5 children developed bilirubinuria during the course of the investigation, and in 4 cases tests were positive on more than one occasion. As soon as a suspicious or positive result occurred the child was isolated and kept in bed until 3 successive negative tests had been obtained. A detailed summary of findings in all positive cases is given in the accompanying Table. Unfortunately, in only two instances was it possible to collect blood for the estimation of serum bilirubin. It must be pointed out that the degree of bilirubinuria was relatively slight, since Hunter's test is a great deal more sensitive than most other urine tests for bilirubin, a +++ result corresponding roughly to a just-positive iodine ring test. None of the children ever developed jaundice, but K.R. would probably have been recognized as a "subicteric case," since he was passing very obviously dark urine and had a well-defined clinical attack.

Summary of Findings in those Children in Nursery A who showed Positive Hunter's Tests during the Investigation

Name	Age	Date of First Positive Hunter's Test	Serum Bilirubin		Remarks
			Date	Mg./100 c.cm.	
A.W.	4½	March 19	—	—	No symptoms March 21: Liver not felt; no abdominal tenderness
K.R.	4	„ 21	March 21	0·8 (Direct van den Bergh reaction: positive)	March 20: lethargic; anorexia March 21: Vomited; liver not felt; slight tenderness R. hypochondrium
B.F.	4	„ 26	„ 28	0·4	March 28: nausea and vomiting. T. 100°. Liver not felt; no abdominal tenderness
S.L.	2½	April 11	—	—	No symptoms April 12: T. 100° April 15: Urine "dark"; liver definitely enlarged and slightly tender
J.S.	5	„ 23	—	—	No symptoms April 25: Liver palpable but not enlarged; no abdominal tenderness

The only child of those being investigated who developed any symptoms without bilirubinuria was P.B., who vomited once on the night of March 31; her temperature was normal and she was perfectly well the next day. Six other children, not in the series, vomited each on one occasion during the period of the investigation; Hunter's tests, performed the following day, were all negative, and with one exception—a boy who developed a temperature of 101.4° and was not well for about a week—recovery was almost immediate. Vomiting is, of course, not infrequently encountered in children of this age, and it is difficult to ascribe much significance to this symptom alone.

It is thus possible to say that suggestive evidence of liver damage and therefore of infection with the agent of infective hepatitis (known to be present in the community) was obtained in 3 cases in the absence of significant symptoms. The most striking cases were S.L. and A.W., both of whom gave repeated unequivocal positive tests over a period of several days without ever developing symptoms. It is unlikely that either would in the ordinary way have been suspected as possible cases, although S.L. was noticed to have passed dark urine on one occasion 4 days after the first positive test; her temperature would not have been taken had she not been under suspicion because of her bilirubinuria, since she appeared perfectly well. In one other case (B.F.) considerable bilirubinuria occurred two days before the onset of symptoms, and in K.R. a suspicious result was obtained one day before the onset.

The sequence of cases in the epidemic is shown in Fig. 2. If all the children who developed bilirubinuria are included as possible cases, it is likely that A.W., K.R., and B.F. were infected at the same time as the first-reported child victim (P.H.)—presumably by one of the two staff cases that occurred in February—and that S.L. and J.S. were secondarily infected from them. The time of occurrence of the symptomless "cases" is consistent with the known incubation period of 20 to 40 days. No further cases of jaundice have occurred in this nursery up to the beginning of October (5 months after the end of the investigation).

Controls

It was considered advisable to investigate under identical conditions similar communities who had not been exposed to any source of infection for several months. Thirty-two children in two other residential nurseries where there had been no record of jaundice among either staff or children for at least 12 months were therefore tested approximately thrice weekly over periods up to 4 weeks. In 4 isolated cases in one of these nurseries suspicious traces of bilirubin were found, although, so far as was known, all the children were well; but there was no positive result out of a total of 302 tests.

Discussion

It must be admitted that these findings have been obtained in very young children, and at the best remain only suggestive. It is possible that efforts to obtain similar results among an adult community would not be successful. It might also be argued that the children were too young to be capable of complaining of slight subjective symptoms which would certainly be commented upon by adults But the fact remains that definite bilirubinuria occurred among apparently healthy members of a community exposed to the risk of infection, and such bilirubinuria was not present to any significant extent in similar communities not so exposed. It therefore appears possible that infection with the virus of infective hepatitis may be unrecognized even when special efforts to detect cases are made under close medical supervision.

Summary

Suggestive evidence of symptomless attacks of infective hepatitis among a community of young children exposed to risk of infection has been obtained by the repeated use of Hunter's test for bilirubinuria.

My special thanks are due to Dr. G. Hamilton Hogben, medical officer of health for the borough of Tottenham, and to Miss Moody, matron of Tottenham Residential Nursery, Bengeo, Hertford, without whose willing and efficient co-operation this investigation would not have been possible; also to the matrons and staffs of the nurseries at Abberley House, Shelford, and Kensal House, West Wratting, who most generously helped in collecting control specimens from children under their care.

AMPUTATIONS, RE-AMPUTATIONS, AND PENICILLIN

BY

E. N. CALLUM, F.R.C.S.Ed.

Senior Surgeon and Deputy Medical Superintendent, St. Helier County Hospital, Carshalton; Late Senior Surgeon, Ministry of Pensions Hospital, Chapel Allerton, Leeds

This communication is based on some 102 amputations and re-amputations, 90 of which were performed during a 6-months period at the Ministry of Pensions Hospital, Chapel Allerton, Leeds. There were 19 primary amputations and 83 re-amputations; amputations of digits and trimming operations on soft tissues are not included.

Twelve cases operated on previously to the 6-months period were selected as cases which would have been suitable for post-operative penicillin had it been available. The majority of the 83 re-amputations were performed on patients whose original amputations had been carried out under active-service conditions, where the primary consideration was to save life. All the re-amputations were necessary for limb-fitting purposes. Some of these, however, had undergone primary amputations in ideal hospital conditions, only to be subjected to re-amputation because the original stumps were unsuitable for the fitting of artificial limbs. The reason for this is probably the retention in most textbooks of operative surgery of descriptions of classical amputations which should be revered for their antiquity rather than practised by surgeons. An invaluable book on the subject is *Amputations and Artificial Limbs*, by Kelhan and Perkins (Oxford University Press). The operation is not merely the removal of a diseased or mutilated limb, but the first step towards supplying the patient with an artificial limb. As was pointed out by Mr. St. Clair Strange at a meeting of the British Orthopaedic Association (reported in the *Journal*, Jan. 13, 1945, p. 56), the amputation stump is a new and normal organ, upon the perfection of which depend the subsequent health and happiness of the patient.

Careful operative technique, with particular attention to haemostasis, will amply repay the patience and trouble expended. In many cases sepsis in an amputation stump follows haematoma formation, and this can be avoided only by careful technique. Except in extreme urgency, to aim at speed in amputations is folly, and is a relic of the pre-anaesthetic era of surgery. The important points are: (i) snugly fitting anterior and posterior flaps; (ii) avoidance of lateral flaps; (iii) meticulous attention to haemostasis; (iv) drainage for a limited time, usually 24 to 48 hours; (v) careful post-operative bandaging and early stump movements.

It has been stated by Mr. Strange (loc. cit.), quite correctly, that a re-amputation should be approached in the same spirit as, for example, a bone graft, and that adequate time must be allowed after the healing of the original wound sepsis before embarking on the operation. There is, however, an additional important factor with which this paper is concerned—namely, the effect on the patient of prolonged hospital treatment and lack of a limb. Many septic stumps take a very considerable time to heal, only to be re-amputated before an artificial limb can be fitted. The effect of all this is bad for the morale of the patient, besides being a serious economic handicap to himself and the State—delaying as it does his reinstatement as a useful member of the community.

Results with Post-operative Penicillin

For these reasons we have, in certain cases, been performing re-amputations with the help of post-operative penicillin before the original wound had healed, or when it had only just healed. In many of these cases the wounds were of the type that "looked as if they would never heal"—to quote a nursing sister. In none of these cases was operation undertaken in the presence of obviously active inflammation or profuse discharge, and in all cases but one (in which healing was considerably delayed) the organisms present in the discharge were predominantly penicillin-sensitive. In other cases post-operative penicillin has been used on account of a past history of severe infection or of the presence of bone disease, and in these cases operation has been undertaken earlier than would otherwise have been feasible.

The first series (Series A) comprises 34 cases treated with post-operative penicillin, locally in all cases, and in a few instances by the systemic route as well. The local penicillin was administered by means of small-bore rubber tubing with lateral holes, stitched across the wound and coming out at each corner, the flaps being accurately and firmly sutured together. The dosage in most cases was 5,000 units twice daily for 5 days in the case of local therapy, while the systemic course was 15,000 units every 3 hours, also for 5 days, by intramuscular injection. The remaining 68 cases were in the nature of controls, and did not receive penicillin. 47 of these cases (Series B) were "clean," and could, on general surgical principles, be considered safe for operation. The remaining 21 cases (Series C) were more doubtful, and were of the type which would probably have benefited from post-operative penicillin if available.

The results are shown in Tables I to IV. To give an indication of the progress of cases the average periods have been calculated (in weeks approximately) between the time of wounding and the time when first measurements were taken for artificial limbs, and again between the time of the amputation or re-amputation under consideration and first limb-fitting action. This latter time-period gives a very fair indication of the success of the operations under consideration in the three series.

In Table I it will be seen that in Series A these average times are 35½ and 10 weeks respectively. In Series B they are 29½ and 7 weeks; while in Series C they are 35 and 21 weeks. In this last series it should be noted that 8 cases are still unhealed, so that the average times of healing would really be considerably higher if these had not been omitted from the calculation. There were no such failures in the penicillin series (A) or in the "clean" series (B); while the failures in Series C comprise 38.5% of that series, which contained cases very similar to those in Series A. In this paper an amputation is considered to be a failure if the stump remains unhealed for a long period or if re-amputation has to be performed before limb-fitting is possible.

TABLE I.—*Analysis of All Cases*

Series	No. of Cases	Average Time Wounding to Limb-fitting	Average Time Operation to Limb-fitting	Delayed Healing (No. and %)	Unhealed (No. and %)
Series A	34	35½ weeks	10 weeks	3 (8·8%)	Nil
Series B	47	29½ ,,	7 ,,	0	0
Series C:					
(*a*) Relative success	13	35 ,,	21 ,,	11 (84·6%)	
(*b*) Still unhealed	8				8 (38·5%)
(*a* and *b*)	21				
Series B and C combined (unhealed cases excluded)	60	31 ,,	10 ,,	11 (18·3%)	0
Series A, B, and C (unhealed cases excluded)	94	33 ,,	10 ,,	14 (14%)	0
Unhealed cases ...	8				8 (8% of all cases)

Of 90 cases operated on at this hospital during 6 months all have been measured for artificial limbs. Six of the 8 cases still unhealed and 1 of the cases of delayed healing were transferred to this hospital from elsewhere after operation.

Table II gives an analysis of cases in Series A, with types of case operated on and some other details. Where more than three months had elapsed between operation and limb-fitting the cases were considered as instances of delayed healing. It may be noted that only 3 such cases occurred out of 34—that is, 8.8%.

TABLE II.—*Analysis of Series A (Cases receiving Post-operative Penicillin)*

Type of Case	No. of Cases	Details	Average Time Operation to Limb-fitting
Open wounds:			
Successful	16	Penicillin-sensitivity positive in all cases; 3 cases with protrusion of bone	9 weeks
Delayed healing ..	2	Both below knee; one developed haematoma, one became septic	20 ,,
Failures	0		
Bone involved:			
Successful	5	One case with protrusion of bone, 4 with osteitis or osteomyelitis	11 ,,
Failures	0		
Prophylactic penicillin:			
Successful	9	Past history of severe infection	9½ ,,
Failures	0		
Recently healed stumps:			
Successful	1	Past history of infection	7 ,,
Delayed healing ..	1	Above-knee; developed eczema of stump after healing	18½ ,,
Failures	0		
All types:			
Successful	31		9½ ,,
Delayed healing ..	3		16½ ,,
All cases included ..	34		10 ,,
Failures	0		

Percentage of delayed healing, 8·8 (3 out of 34). Best average results were when the penicillin-sensitivity tests were positive.

Table III provides details of cases in Series C, for comparison with Table II. It is obvious that the results in Series A were very much better than those in Series C, although both series contained similar types of case. Even with the 8 failures left out of account, the average time between operation and limb-fitting was 21 weeks in Series C, as compared with 10 weeks in Series A. It is not too much to claim that the difference in these results is due to the use of post-operative penicillin.

In considering cases of delayed healing in Series A and C it is of interest to note that in at least three instances trouble started with haematoma formation, and in one case the penicillin-sensitivity test was negative.

TABLE III.—*Analysis of Series C (Infected, Non-penicillin)*

Type of Case		No. of Cases	Average Time Wounding to Limb-fitting	Average Time Operation to Limb-fitting
Open wounds still present at operation	Healed ..	5	41 weeks	20½ weeks
	Unhealed ..	2		
Infected cases*	Healed ..	5	32 „	21 „
	Unhealed ..	6		
Other factors present†	Healed ..	3	35 „	21 „
	Unhealed ..	0		
All cases ..	Healed ..	13	35 „	21 „
	Unhealed ..	8		

* Those with a history of severe infection of the wound.

† One case had a Charcot ankle, one had foreign bodies in the stump, and the third had had an ulcerated leg for years before amputation was undertaken.

Table IV gives details of the 90 cases operated on during a 6-months period, with comparisons between cases receiving and those not receiving post-operative penicillin. The results are given for the various amputation sites. It should be noted that the most difficult site to obtain a good result is below the knee, all but 2 of the 12 cases of delayed healing being below-knee amputations.

TABLE IV.—*Comparison of Results at Various Amputation Sites (in 90 Cases during 6-months Period)*

Site of Amputation or Re-amputation	Penicillin Series.		Control Series		All Cases Combined	
	No. of Cases	Average Time Operation to Limb-fitting	No. of Cases	Average Time Operation to Limb-fitting	No. of Cases	Average Time Operation to Limb-fitting
Above elbow	2	10½ weeks	6	9 weeks	8	9½ weeks
Below elbow ..	2	11 „	10	5½ „	12	6½ „
Above knee ..	19	9 „	11	7½ „	30	8½ „
Below knee ..	11	12 „	29	12 „	40	12 „

Conclusions

The best indications of the success of an amputation or re-amputation are: first, the shortness of time between operation and readiness of the stump for limb-fitting; secondly, the subsequent behaviour of the stump under the strain of wearing an artificial limb. Time alone can show the latter, but the former can be worked out quite easily and gives a reasonable index of the degree of success. It may be added that a rapidly healing stump is usually sounder than a slowly healing one.

Broadly speaking, these series give us the results in 3 types of case. First, potentially or actually infected cases receiving post-operative penicillin; secondly, uninfected cases not receiving penicillin; and, thirdly, potentially or actually infected cases not receiving post-operative penicillin. It is evident that in the uninfected cases the results were best, but they were only slightly better than in the infected cases receiving post-operative penicillin; the relevant average times of healing were 7 and 10 weeks respectively. It should be remembered that many of these infected cases had been grossly infected, and could not have undergone re-amputation for weeks or months later had it not been possible to administer post-operative penicillin; yet there were no failures in this series and only 3 cases of delayed healing. In the third series, even with 8 failures not included, it is found that the average healing-time was 21 weeks—more than twice the period in similar cases which had received penicillin after operation.

From these results it can be claimed that the use of penicillin not only shortens the time between operation and limb-fitting, but makes it possible to operate on doubtful cases considerably earlier than would otherwise be feasible. Convalescence is shortened and a far better prospect of success is assured.

Summary

A report is given of 102 amputations and re-amputations. Of these 55 were infected or potentially so at the time of operation; 34 of them received post-operative penicillin and 21 did not. The results show that, in selected cases, it is possible to operate on infected cases much earlier with than without penicillin, and with good prospects of success. In this way convalescence can be considerably shortened, and the patient can start earning his living earlier.

It is pointed out that there were no failures in the penicillin series, and in only 8.8% of this series was there delay in healing of stumps. Emphasis should be laid on the necessity for penicillin-sensitivity tests before operation.

Careful attention should be paid to operative technique, and operation should not be undertaken in the presence of active inflammation or profuse discharge from a granulating wound.

My thanks are due to the Director-General, Medical Services, Ministry of Pensions, and the Medical Superintendent at Chapel Allerton for permission to publish these series; also to my colleagues—especially Mr. A. Lawson Light, who performed some of the operations—for helpful criticism, and to the pathological department and office staff for their assistance.

DESCENT OF THE TESTIS IN RELATION TO TEMPERATURE

BY

ALEC W. BADENOCH, M.D., Ch.M., F.R.C.S.

Wing Commander, R.A.F.V.R.; Surgeon, Metropolitan Hospital, London

The abdominal position of the foetal testis was known to Galen (Frankl, 1895), but Baron Haller (Hunter, 1837) and John Hunter (1837) really first focused attention on this point and began the stream of literature, which has flowed on in such quantity from observers, on all aspects of development and descent. The facts are few and not greatly in dispute; the fancies prolific and constantly recurring.

The Position in Mammals

The descent of the testis is peculiar to mammals. In all animals, up to and including reptiles and birds, the testis lies high up in the abdomen, and in some of the more primitive mammals, such as the Monotremata (duck-billed platypus and spiny ant-eater), this position persists. In the higher groups the testis lies in the false pelvis. Most of the Edentata (sloth, ant-eater, and armadillo), some of the Insectivora (shrew), the Cetacea (whale and porpoise), and the Sirenia (seacows) have primary abdominal testis with no inguinal fold. In marsupials (kangaroo and wallaby) the testis lies in the suprapubic region, in a well-developed pouch with a closed processus vaginalis. According to Andrews and Bissell (1934) this is really inguinal and represents the earliest extra-abdominal position. In rodents, some of the Insectivora (mole and hedgehog), and Cheiroptera (bats) the testis is intra-abdominal in the resting phase of the sexual cycle. During the rutting season it is extruded by unstriated and retracted by striated muscle; there is no true vaginal process. In the Ungulata, Carnivora, and Primates there is a true vaginal process, and the testis is extra-abdominal. The elephant is an exception, the testis being inside the abdomen; and in some—e.g., the stag—the testis is retracted at other than the rutting season. It has been said that the processus vaginalis is occluded only in man and some of the higher monkeys, but occlusion must sometimes occur in other animals, since hydrocele has been reported in dogs and bulls.

Cause of Migration

There is no physiological reason why the testis should not leave its primitive position in the abdomen. Certainly as regards its spermatogenic function it plays no part in the general economy of the body, and, as Crew says, it belongs to the race rather than to the individual. When discussing the problem of its extra-abdominal position Herbert Spencer (1866) wrote: "We cannot consider it an adaptive change, since there seems no way in which the production of sperm cells, internally carried on in a bird, is made external by adjustment to the changed requirements of mammalian life. Nor can we ascribe it to the survival of the fittest, for it is incredible that any mammal was over-advantaged, in the struggle for life, by this changed position of the organ." I think all would be in agreement with the last sentence, but the previous one is now known to be incorrect.

Influence of the Scrotum on Spermatogenesis

In any animal in which the testis normally descends, in order that it may attain full development and function, it must reach and occupy the terminal part of its destined course. Griffiths (1895) showed that if the testis of a dog was replaced in the abdomen it diminished in size and lost its spermatogenic function. In 1924 Moore performed a series of experiments at the Hull Zoological Department, Chicago, using guinea-pigs, rabbits, and rats. In these animals there is a wide-open connexion between the scrotum and the peritoneal cavity, and the testis can be kept in the peritoneal cavity without in any way interfering with its nerve or blood supply. Moore found that in testes retained in the abdomen for as short a time as seven days there was total disorganization of the germinal epithelium of the seminiferous tubules. The usually well-defined tubular lumen was practically filled with a mass of cells thrown out from the epithelium. Some of the cells could be seen in outline only. Others showed fragmentation of the nucleus, and protoplasmic masses were localized in a granular debris. After 14 days' peritoneal retention most of the debris resulting from degeneration had been removed from the tubules, although a few cells could still be seen. At the end of 21 days little remained of the tubules except the reticulum, with the cells of Sertoli lying against the inner border of the basement membrane. A typical cryptorchid had therefore been produced in three weeks. Subsequent examination of testes showed that there was a progressive diminution in the size of the tubules so that they had shrunk to about one-third of their former diameter. Concomitantly, the interstitial cells had become more prominent and were arranged in masses between the now more widely separated tubules. Certain testes were then replaced in the scrotum, and in a few months the tubules in these had returned to normal. These experiments were confirmed by Wangensteen (1927), who used immature and young dogs for the purpose.

It follows, therefore, that the scrotum exerts a peculiar and striking influence on the testes—an influence that is necessary not only for the differentiation of the germ cells but also for the retention of cells already differentiated.

Influence of Temperature on Spermatogenesis

Meek (1920) noted that the length and periodicity of the spawning of certain fish varied with the temperature of the water. Crew (1921–2) first drew attention to the efficiency of the scrotum as a temperature-regulating organ. It is a pouch of very thin skin well supplied with sebaceous glands. The dartos is firmly attached to the skin, is of non-striated muscle, and quickly responds to changes of temperature. In warmth the scrotum becomes lax, flaccid, and pendulous, while in cold it is corrugated, short, closely invests the testis, and draws it against the body wall. Further, there is no fat in a normal scrotum. When the scrotal skin becomes thickened by a pathological condition, such as elephantiasis, atrophy of the testis occurs. Fukui, in 1923, applied heat to the testis in various forms such as hot air, arc light, and sunlight, and found that exposure to excessive heat was followed by degeneration of the seminiferous tubules. He then elevated both testes of an animal into the peritoneal cavity and artificially cooled the external area in the region of the testes on one side. On examination of the testes after a few days he found that the cooled one was normal while the other showed degeneration of the tubules.

In 1924 Moore and Oslund insulated the scrotum of a ram against heat loss by loosely encasing it in a woollen garment, with a waterproof cover sewed to fit the contour of the scrotum and suspended by artificial supports to prevent abnormal pressure. After 80 days the testes were found to be devoid of spermatozoa; many tubules were in an advanced stage of degeneration, and in others the germinal epithelium had disappeared. As Moore says, "the animal had sterilized itself with its own body heat."

Subsequently Moore and Quick (1924) performed a series of experiments on rats, rabbits, and guinea-pigs and found the scrotal temperature was appreciably lower than that of the peritoneal cavity in each case. They applied hot-water pads to the external surface of a guinea-pig's scrotum, raising the temperature approximately 7 to 8° C. above normal, and on examining the testes in 10 days' time found severe tubular degeneration.

Hill (1937) has made the interesting observation that when the ovaries of mice are grafted on to the ears of castrated male mice the atrophied vesicles and prostate are restored to almost normal. Abdominal transplants have no effect. The inference is that the lower temperature of the ear (similar to that of the scrotum) has stimulated the ovary to produce androgen. Hill suggests that the environment may well condition the production of the specific compounds of the gonad.

Temperature in the Human Scrotum

Harrenstein (1928) performed experiments on 16 children, between the ages of 1 and 11 years, on whom an operation for inguinal hernia or retained testis was being done. He found a considerable difference between the intraperitoneal and scrotal temperatures in each case, the average being 4.9° C. and 3.5° C., depending on whether a short- or long-bulbed thermometer was used.

I have recently carried out temperature recordings in 30 male adults operated on for inguinal hernia. Two long-bulbed laboratory thermometers registering degrees centigrade in tenths were employed. The hernial sac was dissected clear from the cord and opened. A finger was passed downwards into the scrotum, along the cord, until the tip was in approximation with the body of the testis. Both thermometers were introduced through the opening in the sac into the peritoneal cavity, until each bulb was lying on the floor of the iliac fossa. In two to three minutes the temperature on each thermometer appeared stabilized, and a reading was taken. One thermometer was now withdrawn and passed into the scrotum. Readings were recorded at one-, two-, and three-minute intervals. The thermometer was then removed and again introduced into the peritoneal cavity, a further reading being taken at the end of

TABLE I.—*The Intrascrotal and Peritoneal Temperature Recordings in 25 Adults*

a minute. The majority of cases were operated on under block local analgesia, occasionally supplemented with 0.5 g. of pentothal intravenously. In no case was any deleterious effect produced. Table I shows the results in 25 cases with a three-minute record of scrotal temperature. Table II shows the results in 5 cases when the thermometer was withdrawn from the scrotum after one-minute and two-minute interval recordings of the temperature in the pubo-inguinal region were taken.

From these two tables the following facts are deduced. In each case the temperature is lower in the scrotum than in the iliac fossa. This varies from 0.8° C. to 3.7° C., with an average difference in 30 cases of 2.2° C. The temperature in the pubo-inguinal region in each of 5 cases is higher than that in the scrotum but an average of 1.4° C. lower than that in the iliac fossa.

Discussion

Is this thermal influence a cause or an adaptation of migration? Many observers (Hart, 1908–9; Crew, 1921–2; Keith, 1933) have taken the view that the cause of migration is mechanical. With changing methods of progression, the dense, compact, suspended testis was gradually compelled to pass from the primitive position towards the inguinal region of the abdominal cavity. It then came to lie in the lymph spaces described by Sabin. With increasing impulsiveness of movement and with the increase in abdominal pressure following the development of the diaphragm, the testis was forced along the lymph tracts until it came to lie in the subintegumental position in the groin. Further impulsive activity produced a hernia of the testis into the scrotum. I do not consider this theory at all satisfactory. It is only in the male of the species that the reproductive gland normally "herniates"; and why should this comparatively small organ be the only one to do so on mechanical grounds? The large group of rodents and the stag, which undoubtedly are as active and impulsive in their movements as any other mammal, have intra-abdominal testes except in the rutting season. I believe that the migration is a search for a lower temperature. In the Monotremata and certain lower orders with abdominal testes, body temperature is much more variable than in the higher mammals. In the whale the amount of subcutaneous blubber would insulate the testis, and the thick skin of the elephant would preclude heat loss. Andrews and Bissell have put forward the view that these two groups are secondary testiconda. We know that eels migrate to breed in the depths of the Saragossa Sea, that salmon and other fish migrate to the upper reaches of mountain streams for their breeding, and that birds migrate to a colder area during their nesting season. It is not unreasonable, therefore, to suggest that in mammals the reproductive gland, instead of the whole animal, migrates for the same specific purpose.

Summary

The position of the testis in the various groups of mammals is discussed.

The influence of temperature on spermatogenesis is reviewed.

Recordings of the temperature in 30 young adults are given.

It is suggested that the extra-abdominal position of the testes is a migration in search of a temperature lower than that of the body.

"FASTNESS" OF STAPHYLOCOCCI, HAEMOLYTIC STREPTOCOCCI, AND PNEUMOCOCCI TO PENICILLIN

BY

E. W. TODD, M.D., D.P.H.

G. S. TURNER, A.I.M.L.T.

AND

L. G. W. DREW

(*From the Serum Institute, Wellcome Foundation, Carshalton, Surrey*)*

In a previous communication Todd, Turner, and Drew (1945) showed that two different strains of staphylococcus became highly resistant to penicillin when subcultured daily in penicillin broth. The resistance of the strain "Oxford H" was increased 3,000 times after 27 subcultures, and the resistance of strain "Staphylococcus A" was increased 250 times after 21 subcultures. This high degree of resistance to penicillin disappeared rapidly when the organisms were subcultured daily in plain broth.

The same methods of investigating (1) the time required to produce "fastness" to penicillin and (2) the temporary or permanent character of this acquired change have now been applied to haemolytic streptococci and pneumococci.

Staphylococcus

The cultivation of strains of "Oxford H" and "Staphylococcus A" in penicillin broth, described in a previous paper, was continued. After 75 subcultures in penicillin broth both the strains were 5,000 times more resistant to penicillin than the original cultures; they both grew in broth containing 400 units of penicillin per c.cm. On subcultivation in plain broth the resistance of both strains to penicillin was rapidly lost.

Haemolytic Streptococcus

Rake *et al.* (1944) subcultured *Str. pyogenes* (Strain C 203, Group A, Type 3) in penicillin broth. After 58 subcultures the dose of penicillin required for "bacteriostasis" had increased from 0.03 to 0.95 unit per c.cm., showing a 30-fold increase in resistance. They do not state whether this resistance was maintained or lost on subcultivation in plain broth.

Fig. 1 shows the results of subculturing Strain C 203 daily in broth containing falling dilutions of penicillin on a 20% range in a total volume of 1 c.cm. The daily variations in resistance were much greater than those obtained with staphylococci (Todd, Turner, and Drew, 1945). This was particularly noticeable at the beginning of the experiment, before any definite increase in resistance was observed. Resistance to penicillin was increased five times after 35 subcultures and four

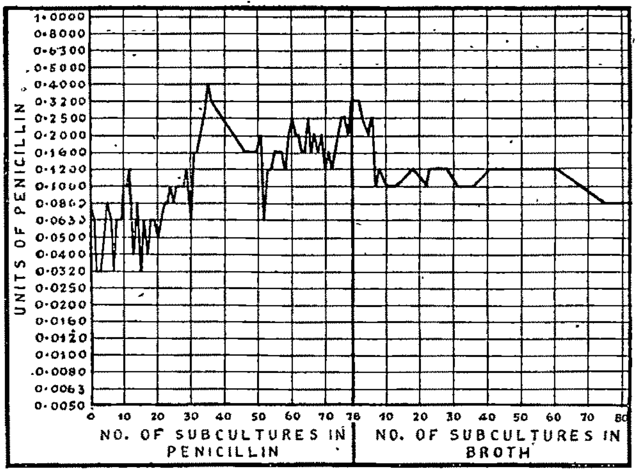

FIG. 1.—Showing increasing resistance on subculture in penicillin, followed by diminishing resistance on subculture in broth. *Str. pyogenes*, Strain C 203, Group A, Type 3.

---

* Seconded from the London County Council.

times after 78 subcultures. On subcultivation in plain broth "fastness" was maintained for two days; it then began to fall until after 76 subcultures the original "bacteriostatic" dose of 0.08 unit of penicillin per c.cm. was again effective. There is, however, considerable doubt whether 0.08 unit per c.cm. was the true "bacteriostatic" dose for the original culture, since smaller effective doses were observed on a number of occasions at the beginning of the experiment. A direct comparison of the original culture, which had been kept in a dry state, with the 82nd subculture of the resistant strain in plain broth gave the following results:—"Bacteriostatic" dose: original culture 0.02 unit per c.cm.; 82nd subculture, 0.08 unit. Nevertheless the general appearance of Fig. 1 suggests that "fastness" of haemolytic streptococci to penicillin is a temporary acquired character which is gradually lost on subcultivation in broth.

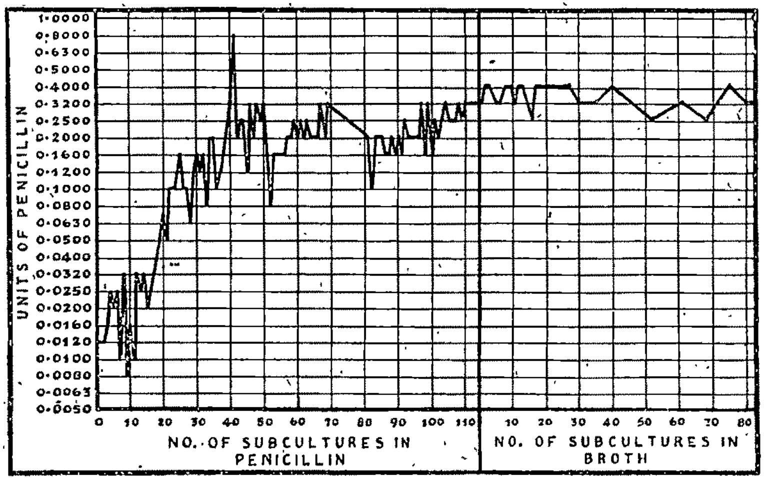

FIG. 2.—Showing increasing resistance on subculture in penicillin, followed by maintained resistance on subculture in broth. Pneumococcus, Type III.

Pneumococci

Rake *et al.* (1944) subcultured Pneumococcus Type III in penicillin broth 55 times, thereby increasing the resistance of the strain to penicillin 30 times. After 32 subcultures of their resistant strain in ordinary blood broth the "bacteriostatic" dose of penicillin remained unchanged.

Fig. 2 shows the results of subculturing Pneumococcus Type III first in penicillin broth and then in plain broth. Resistance to penicillin was increased 27 times after 46 subcultures, and this level was maintained after 114 subcultures in penicillin broth. "Fastness" to penicillin was maintained after 82 subcultures in plain broth. This confirms the observation of Rake *et al.* (1944) that acquired "fastness" of pneumococci to penicillin is a permanent character.

Discussion

Although the number of strains used in these experiments is too small to draw any general conclusions, there are certain facts which seem to be established. The first of these is that staphylococci become penicillin-"fast" much more easily than haemolytic streptococci or pneumococci on subcultivation in penicillin broth. The accompanying Table, which is compiled from the figures of Rake *et al.* (1944) and of Todd, Turner, and Drew, shows a 4,000-fold average increase of resistance to penicillin for five strains of staphylococci, compared with an 18-fold average increase for four strains of pneumococci and a 16-fold average increase for a single strain of *Str. pyogenes*, although the average number of subcultures in penicillin was greater for the pneumococci and streptococci than for the staphylococci.

Table showing the Number of Subcultures in Penicillin Broth required to produce Penicillin-" fast " Cultures, and the Degree of " Fastness " obtained with Various Organisms

Authors	Organism	Strain	Number of Subcultures in Penicillin Broth	Increase of Resistance to Penicillin
Rake *et al.* ..	Staphylococcus	"Smith"	59	6,000 times
" " ..	"	C 1	28	1,000 "
" " ..	"	C 2	28	4,000 "
Todd *et al.* ..	"	Oxford H	72	5,000 "
" " ..	"	A	77	5,000 "
Rake *et al.* ..	Pneumococcus	Type I	54	6 times
" " ..	"	" II	62	6 "
" " ..	"	" III	55	32 "
Todd *et al.* ..	"	" III	114	27 "
Rake *et al.* ..	Str. pyogenes	C 203	58	27 times
Todd *et al.* ..	"	C 203	78	4 "

Secondly, the observation of Rake *et al.* (1944) that penicillin-"fast" pneumococci maintain their "fastness" on subcultivation in ordinary laboratory media, without penicillin, is confirmed. On the other hand a single strain of *Str. pyogenes* lost its "fastness" on subcultivation in plain broth, behaving in this respect more like staphylococcus than pneumococcus.

Summary

Staphylococci are easily made penicillin-"fast" by subcultivation in penicillin broth; they lose their acquired "fastness" when subcultured in plain broth.

Haemolytic streptococci, so far as can be judged from the behaviour of a single strain, are more difficult to make penicillin-"fast" than staphylococci; they also appear to lose "fastness" when subcultured in plain broth in a similar way to staphylococci.

Pneumococci also acquire "fastness" much less readily than staphylococci; they maintain acquired "fastness" when subcultured in ordinary laboratory media.

Medical Memoranda

Hypersensitivity to Quinine and Mepacrine

In view of the great importance and widespread use of chemotherapy in the suppression of malaria at the present time, the following rarity is of topical interest.

CASE REPORT

The patient was an air-crew officer, aged 25, who took one tablet (0.1 g.) of mepacrine hydrochloride at 1 p.m. on Nov. 19, 1944. Two hours later he began to notice a certain itchiness and painfulness of the skin of his hands and feet; and shortly afterwards these and the scrotum, penis, and nipples began to swell. At the same time the skin of his whole body became red and his throat felt as if it was swollen. About one hour after the onset of his symptoms he began to feel hot; he had a slight frontal headache and marked anorexia and nausea, but no actual vomiting. There were no other symptoms. This was the first mepacrine tablet he had ever taken.

On examination his temperature was 104° F. and pulse 96. The skin of the whole body showed a marked generalized erythema, with no blanching on stroking it. The lips were slightly cyanosed. Some conjunctival injection was present. There was considerable oedema of hands, feet, scrotum, penis, nipples, and eyelids, with slight swelling of the fauces. Otherwise nothing abnormal was found.

Treatment with adrenaline, ephedrine, and magnesium sulphate was given, but without any effect. His temperature, however, settled in 18 hours, and all the oedema and erythema had disappeared in 48 hours. The next week the skin of his body generally, and of his scrotum in particular, peeled, and during this time it remained itchy.

His previous history showed that about three weeks before this reaction he had taken one quinine hydrochloride tablet (6 gr.), and this had produced very similar effects to the reaction described above, with the following two differences: (i) the onset of the quinine reaction occurred four hours after he had taken the tablet; (ii) he had had no rise in temperature after taking the quinine.

When the erythema and oedema of the mepacrine reaction had disappeared I scratch-tested him with both quinine and mepacrine suspensions in normal saline, using a normal saline control; marked localized urticarial reactions occurred with both the quinine and the mepacrine, while the control showed no reaction. As a result of these tests he was considered unfit for service in malarious areas.

Such a condition must be very rare indeed, and I can find no reference to this double hypersensitivity in any textbook available to me at present. In fact, in *Memorandum on Medical Diseases in Tropical and Subtropical Areas* there occurs this statement: "Those with an idiosyncrasy to quinine can take mepacrine with impunity. Mepacrine appears to provoke no similar condition."

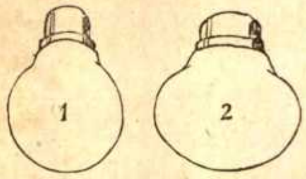
A Source of Error in the Determination of Cell Counts

The flatness of the cover-slips used for counting-chambers is usually taken for granted. It is perhaps not as widely known as it might be that slips which are not flat are occasionally met with. As all such slips are ground flat, one can only assume that they warp after manufacture as the result of internal stresses. Inaccurate cell counts result.

A degree of deformity too small to be perceptible by inspecting the cover-slip edge-on may cause gross inaccuracy. Thus a slip which is only 10μ "off the flat" at the highest point of the convexity will cause an inaccuracy of 10% if the correct depth of the counting chamber is 0.1 mm. A curved cover-slip, used sometimes with the convexity upwards, sometimes downwards, will cause puzzling fluctuations in the cell count of the same patient.

Once a cover-slip has been found to be defective it may be thought advisable to determine the degree of inaccuracy with a view to adjusting counts that have previously been made with it. This is possible only when one can be sure that the curve has been upwards or downwards in all estimations, when the amount by which the curve is off the flat, expressed as a percentage of the correct chamber depth, can be deducted from or added to the counts, as the case may be. If, as has probably been the case, the convexity was sometimes upwards and sometimes downwards, measurement of the degree of deformity will at least show whether it is so great as to place previous counts beyond the permissible limits of inaccuracy.



Distortion of the image of a spherical bulb caused by a deformity of 10μ off the flat.

RECOGNITION OF DEFORMITY

Any such deformity may be easily and quickly perceived and measured by the following method:

1. Hold a corner of the cover-slip lightly between the tips of thumb and forefinger.
2. Stand with the back towards a lighted lamp, and about 1 metre from it.
3. Hold the slip at arm's length, and at such an angle that the reflection of the light bulb can be seen in it. If the slip is deformed the image will be distorted. Such deformation is usually cylindrical, resulting in an image which is elongated or compressed in one axis so that a circular light-bulb appears oval.
4. Hold the slip with the concavity facing the eye as shown by an elongation of the long axis of the oval reflection.
5. Note by what proportion approximately the long diameter exceeds the short. Then, assuming that the distance between eye and slip is 30 in., it may be shown, by reasoning beyond the scope of this paper, that if the excess is 28% the slip is 10μ off the flat (see Fig. 2), if 12½% it is 5μ, and if 6% it is 2½μ. In practice an approximate estimate of this excess is sufficient.

The whole process is a matter of a few moments, and large numbers of slips can be examined in a short time.

The presence and extent of such deformity can, of course, be determined with the aid of a microscope with a calibrated fine adjustment. A few small drops of a solution of a coloured substance—e.g., ink—are allowed to dry on the surface of the slip, which is then placed, coloured surface downwards, in position on the counting-chamber. The dried ink is first focused, then the ruled squares, the fine adjustment being read on each occasion and the true depth of the chamber noted. The correct depth subtracted from this will give the figure required.

The first method described has the advantage of simplicity and speed, and does not entail the use of a microscope with a calibrated fine adjustment.

St. Giles' Hospital (L.C.C.), Camberwell. BERNARD FREEDMAN, M.B., M.R.C.P.

Salivary-gland Tumour of the Upper Lip

The following record of a case of some rarity may be found of interest.

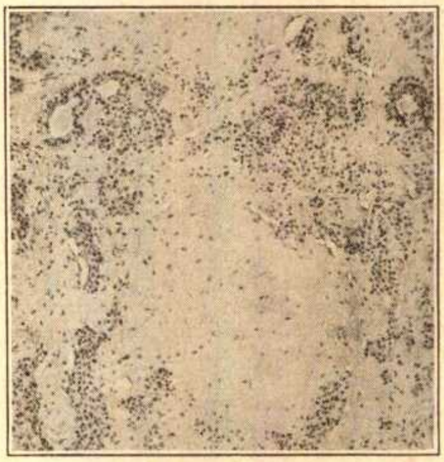
CASE REPORT

A girl aged 18 came under my care in the Royal Infirmary, Edinburgh, in March, 1940, on account of a painless swelling of the upper lip which had been present for many years but had become larger and rather disfiguring recently. It was centred strictly in the midline and protruded on the buccal surface, covered by normal mucous membrane. Using a local analgesic, a transverse incision was made through the mucous membrane, and a solid round tumour, one inch in diameter, was enucleated very easily and completely. The wound was sutured and healed without difficulty, a perfect cosmetic result being obtained.

Histological examination demonstrated the characteristic appearance of a mixed tumour of the parotid (see Fig.). There were hyperchromatic epithelial cells, arranged in the form of alveoli and in solid masses, and a stroma showing the appearance of the so-called cartilage. There was no evidence of malignancy.

COMMENT

The mixed tumour of the salivary glands occurs most frequently in the parotid and less so in the submandibular and sublingual glands, but it also arises in uncommon sites such as palate, tongue, pharynx, larynx, neck, face, orbit, scalp, auditory canal, lacrimal gland, and lips. Sir James Paget in 1851, according to Cade (1937), was the first to describe a parotid tumour in the lip, and of the cases noted since then in the upper and lower lips four were recorded by Wood (1904), one by Schreiner and Mattick (1929), one by Patey (1930), two by Ahlbom (quoted by Cade), and four by Robbins (1943). An aberration in the development of the salivary-gland tissue may possibly account for some of the unusual positions. Ahlbom (1935), however, believed that the tumours in all sites should be classified as mucous-gland and salivary-gland tumours, in which case a tumour of the lip can be explained as arising from a mucous gland and not from an aberrant portion of parotid tissue. In his opinion, also, such tumours are quite benign at the age of the patient here reported.



A photomicrograph of the specimen.

I wish to thank Dr. R. F. Ogilvie for the histological examination and Mr. D. Smith for the photomicrograph. I am indebted to Mr. John Harkness, who saw the patient with me and actually suggested the correct diagnosis.

Reviews

A HISTORY OF MEDICINE

A History of Medicine. By Douglas Guthrie, M.D., F.R.C.S.Ed. (Pp. 448; illustrated. 30s.) London: Thomas Nelson and Sons.

Throughout the ages the Genius of Medicine has frequently changed her home. Born in Sumeria out of priestcraft and superstition, her migration to Egypt did little to redeem that origin. It required the clear intellectual atmosphere of Greece to instil some measure of reason and a capacity for observation. The subsequent extensions to Alexandria and to Rome were entirely Greek in inspiration. As Rome declined, the persecuted Nestorian Christians carried that heritage first to Edessa and then to the court of Haroun-al-Raschid. Hence arose Arabic medicine, which carried on the tradition for several centuries. Only at Salerno was the older Hippocratic method followed, and as this was carried out by progressive teachers its star shone brightly in a dark age from 1096 to 1270, to be eclipsed by the rise of Montpellier, which adopted the Arabic tradition. This tradition had spread far beyond the Arabs themselves; thus the celebrated Maimonides of Cordova was a Jew. After the rise of Montpellier came that of Padua, an offshoot from Bologna. All these migrations are well described in Dr. Douglas Guthrie's *History of Medicine.* Coming to the Renaissance he truly says "it was a change in the entire outlook of thinking men who sought to escape from the tyranny of dogmatic scholasticism. . . . There arose a demand for freedom of thought, a new standard of human dignity and a philosophy of living." Appropriately said in view of the recent attempts to detract from its accomplishments. The centre of the new learning was Florence, which except for Athens has done more to free the human mind from its self-imposed shackles than any other city. But in medicine at the hands of such men as Linacre all that was attempted was at first a simple revival of Greek learning; no new observations were thought necessary. Revival of interest in the study of anatomy was initiated by the artists, particularly Leonardo, and not by the physicians.

The year 1543 marks the birth of modern science; Copernicus revolutionized our conceptions of the universe, and Vesalius published his great anatomical textbook *De Fabrica.* The pace of advance quickened. William Gilbert initiated experimental physics, and Harvey applied them to physiology. England also rejoiced in great clinicians such as Glisson, Willis, and Sydenham. The founders of the Royal Society gave a scientific cast to medicine. The early 18th century saw the rise of Leyden under Boerhaave, and English physicians resorted there rather than to Padua. A little later came the rise of the Edinburgh School, marred unfortunately by bitter quarrels. The beginning of the 19th century witnessed the undoubted leadership of the French school, particularly in Paris. A few years more and the clinicians of London and Dublin bore the palm, while the later half of the century was marked by the dominance of the Viennese and German schools. This ascendancy was waning even before Germany elected to shut herself out from the comity of science. It looks as if the future leadership may rest with the United States, with its wealth and capacity for organization. The Mayo Clinic is an exemplar of the new medicine. Fortunately the leading American physicians are becoming alive to the danger of the individual patient being subordinated to the mighty machine they have created. It is interesting to speculate on the causes of these repeated migrations. Political changes can have a disruptive effect, but on the constructive side can do little more than provide a stable enviroment. Sometimes it is a single man, like Boerhaave, whose individual genius had a magnetic attraction, or a group of men like the quartette of Osler, Welch, Halsted, and Howard Kelly, who created Johns Hopkins Hospital's pre-eminence. Always the man; one thinks of the unfavourable conditions under which Michael Foster created a great school of physiology at Cambridge. The decline of a school, on the other hand, is often due to complacent "ancestor worship."

Though the theme of migrations runs through Dr. Guthrie's book, he casts his net widely to include all aspects of medicine. To do this in reasonable compass without reducing it to a catalogue is no light task, but he has achieved it by skill and discrimination. His style is attractive and pleasant to read, and the pages are lightened by admirable pen-portraits of outstanding personalities. His erudition is free from pedantry. Rapid technical advances in medicine are tending to diminish interest in its cultural aspects. Dr. Guthrie strongly holds that a study of medical history would tend to correct this and give a due sense of proportion. Formal lectures are hardly possible in the overcrowded curriculum. The simplest plan is that adopted by Sir Norman Moore, who interpolated interesting historical data relevant to the case under consideration.

The volume is admirably produced in this age of so much slovenly work. It is enriched with 72 plates collected from many sources, and a map of the migrations. There is a classified bibliography of the more important references, and (needless to add) a full index. We hope the book will have the success it deserves.

W. L.-B.

RHEUMATIC DISEASES

The Rheumatic Diseases. By G. D. Kersley, M.D., F.R.C.P. With foreword by Sir Francis R. Fraser, M.D., F.R.C.P. Second edition. (Pp. 120; illustrated. 15s.) London: William Heinemann (Medical Books) Ltd. 1945.

The appearance of a second edition of this little book is an indication that it has been found a useful guide to the manifold aspects of rheumatism. It is unfortunate, however, that the new edition should be marred by so many misprints, mostly trivial, but some more serious, such as the recommendation to give 1–2 *gm.* of thyroid extract twice a day when grains are evidently intended; even in the bibliography there is evidence of failure to verify the references.

The clinical features of typical examples of the various types of rheumatic disease are clearly described, and the pathology is discussed with special reference to them, so that the reader may visualize the influence of the disease on the tissues of the patient and the principles of treatment. A well-balanced comparison is drawn between primary and secondary or focal forms of rheumatoid arthritis, and the author favours the view that sensitization is probably an important factor. Many authorities are quoted on different subjects, often giving conflicting opinions which may be found confusing by the ordinary reader, and a clear and perhaps dogmatic exposition of the author's own practice and experience would be of greater service.

The description of physical methods of treatment and their rationale is good and will prove most helpful to the general practitioner; they will be found of greater value in many rheumatic disorders than the usual medicines or "rubbing bottles" so often expected by the patient. It would have been an advantage if such physical methods as can be adapted for home use had been described in more detail with this end in view. The account of the various massage techniques will be found useful to the doctor, who, if he is to ensure the best results, should be able to describe the object to be attained and the best methods of securing it. The account of the methods in use at the spas is clear, convincing, and free from exaggeration. The book is lavishly illustrated, though some of the reproductions of skiagrams are poor.

THE EOSINOPHIL CELL

L'Éosinophilie Générale et Locale. By L. Dérobert. Preface by Prof. M. Duvoir. (Pp. 238. No price given.) Paris: Librairie J.-B. Baillière et Fils. 1942.

This monograph is written in the sound tradition of the classical French thesis, which summarizes the literature of a restricted and often recondite branch of medicine. It is addressed to the experimental haematologist and pathologist rather than the general reader, and it provides a useful quarry of references and ideas. Dérobert's own researches have been chiefly concerned with a study of the tissue eosinophils in hyperpyrexia, and after the inhalation of pepper and the active principles of pepper. He believes that eosinophil cells may originate both in the bone-marrow and in the tissues, and he supports the generally accepted view that the function of the eosinophil cell is to deal with foreign or altered proteins in the body. The subject is highly technical and the book is not easy reading. It leaves one with the impression that, though a great deal of work has been done, we still have little precise knowledge about the life story of the eosinophil or the nature of its prominent granules. The standard methods of examining the blood and the tissues do not seem adequate for the solution of these problems, and we must wait on more novel or refined techniques for further advances.

MOSQUITOES OF THE AUSTRALASIAN REGION

Keys to the Mosquitoes of the Australasian Region: Including a Synopsis of their Distribution and Breeding Habits. By Kenneth L. Knight, U.S.N.R., Richard M. Bohart, U.S.N.R., and George E. Bohart, U.S.N.R. National Research Council: Division of Medical Sciences. (Pp. 71. No price given.) Issued by the Office of Medical Information, Washington. July, 1944.

The systematic entomologist is often accused of counting hairs, but it is safe to say that without his labours little progress could have been made in the study of disease transmitted by insects. This applies especially to the mosquitoes, where the habits of the different species play such a large part in the transmission of disease, and whose importance as vectors of malaria, yellow fever, filariasis, dengue, and possibly other tropical diseases makes their identification one of the first essentials to any research connected with the control of these diseases. Lieuts. K. L. Knight, R. M. Bohart, and G. E. Bohart, of the U.S. Naval Medical Research Unit, are therefore to be congratulated on their most useful revision of the Australasian Culicidae, the result of eighteen months' work in the regions concerned. The Culicidae of many parts of the world, and especially the anopheles mosquitoes, have now been exhaustively studied, and their identification made possible to all and sundry by the publication of authoritative synoptic tables. Even the difficult South American forms have at last been reduced to something like complete order. There still remained, however, a much-needed authoritative synopsis of the no less difficult Australasian species, now clearly and with precision set forth in the reference work published in Washington.

The area dealt with is the Australasian faunal area proposed by Wallace and modified by Swellengrebel and Rodenwaldt (1932), and includes, besides Australia, the Moluccas, New Guinea, and a large part of the Pacific, extending to the Hawaiian Islands, the Marianas to the north, and the Taumoto Archipelago (Society Islands) to the east. New Zealand, South and Western Australia, which possess a large endemic fauna of their own and were far removed from the zone of military activity, are not included in the revision. The whole of the Culicidae are dealt with, in all some 250 species and subspecies (8 *Bironella*, 41 *Anopheles*, 5 *Megarhinini*, 13 *Uranotaenia*, 3 *Hodgesia*, 28 *Tripteroides* (*Rachionotomyia*), 14 *Mansonia*, 100 *Aëdes*, 2 *Aëdeomyia*, 2 *Ficalbia*, and 42 *Culex*). Zoologically the most interesting feature of the fauna dealt with is the absence of certain genera familiar to students of the Oriental species—e.g., *Leicesteria*. But, as the authors note, of the nine genera given by Edwards (1924) as not represented, three have since been recorded. To the malariologist a feature of interest is the now quite large list of species of *Bironella*, that peculiar group of primitive anopheles uniquely confined to New Guinea. Following the various synoptic tables of the different genera is a list giving the distribution and recorded larval habitat of each of the species dealt with. The publication should be of the greatest value, and most helpful to all who may have to do with the identification or control of mosquitoes in this important zone.

Notes on Books

A little book *The Attendant's Guide*, by EDITH M. STERN (Oxford University Press; 3s. 6d.), might well be issued by mental hospitals to their junior nurses. It gives pleasantly worded advice about the handling of the patients, and about most of the problems that are likely to come the way of the mental nurse. Most handbooks of nursing tend to be uninspired and dryasdust on the subject of the attitude of the nurse to her patients, in contrast to which this booklet shows a refreshing humanity informed by knowledge and sense.

The Child Welfare Department of University College Hospital, London, has issued a useful pamphlet on *The Management of Older Babies* (post free 4d.). It covers the period of mixed feeding, from 5 months to 2 years, and deals not only with feeding but with such matters as training in good habits, play, teething, and prevention of illness. A useful section on the need of affection strikes just the right note.

Preparations and Appliances

AN IMPROVED ARTIFICIAL PNEUMOTHORAX NEEDLE

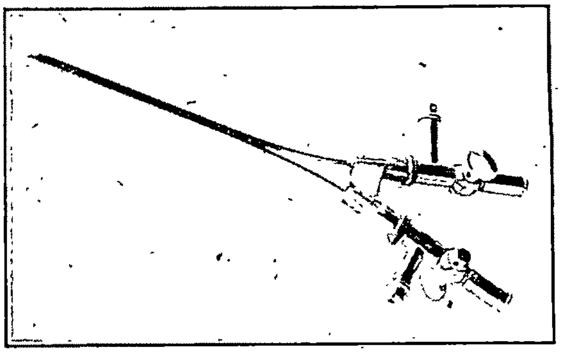
Dr. ALASTAIR ALLAN writes from Greenock:

Recent correspondence in the *Journal* has drawn attention to the occurrence of air embolism, the most dangerous occurrence that may happen during the administration of artificial pneumothorax refills. Air embolism develops with dramatic suddenness and without any useful warning signs; if the occurrence is not immediately fatal, total recovery usually takes place in a few days, but the whole picture is most alarming for all concerned.

With the usual type of pneumothorax needle, after the manometer is observed and read, it is by-passed until the refill has been given, then switched over into the circuit again, and the reading taken. During the refill—the dangerous period—no reading can be observed, and one hopes the point of the needle is still within the intrapleural space: usually it is, but when it is not accidents may happen without warning.

Cameron[1] urges "intelligent use of the manometer" to reduce risks, and Burrell[2] also emphasizes the importance of the preliminary manometer reading. The manometer supplies visible evidence of the presence of the needle-point within the intrapleural space, and it is illogical to be deprived of this visual sign when it is most required—during the actual refill.

Artificial pneumothorax as a specific therapeutic procedure was first carried out by Forlanini in 1888[3] by a method similar in principle to present-day methods but without a manometer. This handicap was removed by Saugmann in 1904, who was the first to use a manometer to record the intrapleural pressure. Artificial pneumothorax apparatus has remained unchanged in principle since then, and the only changes have been various minor modifications. It may therefore be of interest to describe a needle I have been using, the main purpose of which is to reduce the risk of air embolism. It is simply a double needle with two complete and separate air channels; one is led to the manometer by rubber tubing, the other to the air-flow bottle of the A.P. apparatus. The illustration is approximately half-size linear.



When in use a constant manometer reading of the intrapleural pressure is obtained, before, during, and after the refill; and (it should be unnecessary to add) if no reading can be obtained, then no refill should be administered at that site. One has to experience the feeling of confidence which results to appreciate its value.

The only criticism which might be levelled at this needle is the increase in size of the puncture it produces. Theoretically this is true, but in actual practice it is negligible. "Humanity and common sense call for anaesthetization of the needle track,"[1] and this has always been my practice, and the increased size of the needle can genuinely be discounted. It may be noticed from the illustration that the shape of the point causes the end of one channel to be about 1 mm. longer than the other, and the longer is the one I always connect to the manometer: a "V" point instead of a bevel would bring both channels to exactly the same level. This is probably of theoretical importance only.

The needle was made for me by Vicarey, Davidson and Co., 162, Bath Street, Glasgow, C.2. My thanks are due to Dr. Alexander Johnstone, Medical Officer of Health, Greenock, for permission to publish this.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY NOVEMBER 3 1945

THE DISCOVERY OF X RAYS

This year is the centenary of Röntgen's birth, and this next week the fiftieth anniversary of the birth of radiology. The *x* rays were discovered in the late evening of Nov. 8, 1895, by Wilhelm Conrad Röntgen, professor of physics in the University of Würzburg. Röntgen handed in his famous "Preliminary Communication" to the Physical-Medical Society of Würzburg on Dec. 28, and it was published at once. On Jan. 6, 1896, the news was cabled from London to the world, and within a matter of days the practical application of Röntgen's discovery to medicine had been confirmed. The science of radiology was born, and if it did not, like Athene, spring fully armed from the brain of its begetter, it at least lost no time in providing for itself a worthy and rapidly improving armamentarium.

As it is often said that the discovery of the *x* rays was an accident, it is only fair to Röntgen's memory that we should regard for a moment the accomplishments of his predecessors and his contemporaries. In this brief recital of the fundamental discoveries British science shines with a very brilliant light. Hauksbee not only made improvements in the air-pump, but was also the first to produce an electrical discharge in a vacuum (1709). William Morgan, a doctor and one of the greatest of actuaries, did a highly original experiment by which he demonstrated that the quality of the rays produced in a partial vacuum depends on the hardness of the tube (1785). Goldstein (1876) introduced the term "cathode stream" for the rays which are emitted from the cathode when an electric discharge is passed through a partial vacuum, and Sir William Crookes really laid the foundation of atomic physics by his demonstration that these rays could be deflected by a magnet, and that they therefore consisted of electrified particles of matter. Crookes must have produced *x* rays very frequently without realizing their nature, and he actually noticed—and complained of—the fogging of photographic plates in the neighbourhood of a Crookes tube in action. Sir Herbert Jackson invented in 1894 a focus tube for use in his experiments on phosphorescence, and *x*-ray photographs were taken with this original tube after the announcement of Röntgen's discovery. The early researches of Sir J. J. Thomson were carried out with Crookes and Lenard tubes. It was Röntgen's discovery which first focused the chief attention of physicists on the effect of various types of rays on gases, and Thomson himself said in 1896 that the discovery appealed "to the strongest of all human attributes—namely, curiosity."

Röntgen was a Rhinelander who was born in 1845, so that this year marks the centenary of his birth. In 1888, when he was called to the chair of physics at Würzburg, he had already held three professorships. He spent twelve happy years at Würzburg, and he left it only under pressure in 1900 to fill the corresponding chair in the Bavarian capital. Röntgen was a hard worker, and his papers were numerous and marked by brevity, sincerity, and accurate work. His other contributions to physics, though important enough in their way, were outdistanced by his single great discovery.

Röntgen began serious work on the cathode rays towards the end of October, 1895. Even at that time barium platino-cyanide was in common use as a test for these rays, and he was working with a Crookes tube which was covered with a black paper screen, opaque to all known rays. On Nov. 8, 1895, while he was testing the opacity of this screen, he noticed that some crystals of the fluorescent salt of barium which were lying near were showing active fluorescence. It seems very probable that the discovery of *x* rays at that particular time depended upon Röntgen's reaction to this observation, which must have been made previously by other workers. By moving the crystals outside the range of the cathode rays he at once confirmed the fact that he was dealing with a new kind of ray. By placing various bodies in the path of the rays he showed that their opacity was roughly in direct proportion to their density, and when he placed his hand in the path of the rays and saw the shadow of the bones on the screen of barium platino-cyanide he was quick to realize that by substituting a photographic plate for the screen he could obtain a permanent "shadowgraph" of the interior of human tissues. The first *x*-ray of a part of the body was the photograph of Frau Röntgen's hand. There appears to be no truth in the theory advanced years later by a former student of Röntgen that a series of coincidences presented the discoverer with a shadow-photograph of a key placed between the pages of a book. Röntgen admitted a short time afterwards that he was looking for invisible rays. He prosecuted his discovery with the utmost vigour, and in his first communication "On a New Kind of Rays," completed eight weeks later, he presented a sound description of their properties.

After the announcement of the discovery to the world on Jan. 6, 1896, the "new photography" was taken up widely by medical men, by electrical engineers, and by "straight" photographers. In this country within a week of the announcement the first *x*-ray photograph of a human hand was taken by Campbell Swinton and Stanton. The *Lancet* (Jan. 11, 1896) was the first medical journal in this country to comment on Röntgen's discovery, and in its leading article the wit of Mr. Samuel Weller was invoked to pour a cold douche upon the supposed possibilities. By the following week the *Lancet* admitted that the medical application of the discovery was a shade nearer probability. Meanwhile the *British Medical Journal* (Jan. 18, 1896) came out with a carefully considered and laudatory article by Prof. Schuster, of Manchester, and assessed the new discovery at its proper medical valuation. From that date onwards all journals contained numerous articles on *x* rays and their applications. Too much credit can hardly be given to the early British pioneers for their continuous endeavours to improve *x*-ray plant, to reduce exposure time, and to inaugurate *x*-ray therapy. The policy of this

Journal was also progressive and expectant from the start. As early as the beginning of February, 1896, the *British Medical Journal* appointed Mr. Sydney Rowland, of St. Bartholomew's Hospital, as a Commissioner to report on new developments in *x* rays, and week by week he continued to publish his highly interesting articles. Another original pioneer was John Macintyre, of Glasgow, who not only advanced the boundaries of the art of taking "*x*-ray photographs" of the body but who was also the father of fluoroscopy, of the principles now used in miniature radiography, and of *x*-ray cinematography. There are many others who should have a place in any more extensive list, and our gratitude should also go out to those martyrs whose researches led to their disablement and death.

Röntgen himself was the first to make an *x*-ray photograph of a piece of metal, and this led to the wide industrial uses of the method in metallurgy. Even though we chose to regard his discovery as a logical outcome of the work which had been done by others during the preceding thirty years, it was nevertheless the trigger which released the stream of great discoveries in atomic physics. The work of Becquerel, the Curies, J. J. Thomson, Millikan, and Rutherford built the steps which led, we might almost say inevitably, to the conquest of the atom and the unthinkable possibilities of the atomic bomb.

OPERATIVE TREATMENT OF PROSTATIC CANCER

Before his much-regretted death Hugh Hampton Young, of Baltimore, reviewed[1] the success of his operation of radical perineal prostatectomy as a method of curing carcinoma of the prostate—a review that was timely because of the startling appearance of stilboestrol on the therapeutic stage. Young's results are good: in a series of 184 cases there were only 12 deaths, and nearly 50% of the patients are judged to have been cured, 38 cases having been followed up through periods varying from 5 to 27 years. The paper describing these results is long, and gives in much detail and with good illustrations the steps of Young's operation. The prostate, seminal vesicles, adjacent portions of the vasa efferentia, the lowest part of the trigone, and a portion of the urethra at the apex of the gland are removed, the operation being concluded by the approximation of the bladder to the membranous urethra by sutures, and drainage provided by a urethral catheter. Surgeons who have employed the perineal operations for removal of simple enlargements of the prostate will be well aware of certain advantages inherent in this approach, notably a lessening both of shock and of the liability to pulmonary complications in old men, for often with advancing age the chest no longer expands easily, and tidal air is therefore much diminished when the abdominal respiratory movements are involuntarily limited as a result of surgical incision. But they will also realize that an error in technique during the early stages of the operation may lead to tearing of the rectum, though those who are practised in this method will avoid this without difficulty. A more serious danger belonging to the radical prostate-vesiculectomy is the risk of occluding the ureters by sutures placed too close to them during the reconstructive stage of the operation. Another complication, not so serious but in some ways more disastrous, is that the patient may be left with urinary incontinence. This Young considered to be due to injury to the nerve supply to the compressor urethrae, but to other surgeons it seems possible that it may also result from a drag by the bladder upon this part of the urethra; this, by converting it from a cylindrical form into a funnel-shaped passage, prevents the compressor from acting upon it with full effect. Young stated that he had overcome this difficulty; but the fact remains that, even in his own country, his radical operation is not generally employed, and it seems likely that it is the fear of this complication, productive of so much misery when it does arise, which deters other surgeons from adopting what must certainly be described as an operation of precision designed to cure prostatic carcinoma.

The claim that Young's radical operation really provides a cure has a sound basis in the fact that during its early stages the disease frequently has only a local distribution. If it exists alone it begins in the posterior lobe, and as it develops it spreads upwards beneath the trigone and around the seminal vesicles. If it exists in conjunction with benign enlargement of the gland it may also originate in the posterior lobe, or nodules of carcinoma may be found in outlying portions of the adenomata. Young's operation removes the whole of these tissues included within the anatomical prostatic capsule, and also the anterior layer of Denonvillier's fascia, which for some time constitutes a barrier to the disease. The operation is imperfect when compared, for example, with that for carcinoma of the breast, because it is impossible to remove the pelvic lymph glands which drain this field; and it is imperfect, as all operations for cancer are, because of the possibility that distant metastases may already be present before it is undertaken. To these objections Young replied that his statistics show that his operation does effect a cure in a high proportion of cases. Urologists in this country will not dispute this, but they will ask themselves how often they meet with cases in which the disease is still confined to tissues which can be surgically removed. And here they will come up against Young's statement that "cancer of the prostate occurs in at least 14% of all men past 44 years of age." Will they and general practitioners of long experience accept this dictum? Admittedly cancer of the prostate is occasionally diagnosed when, a supposed adenomatous prostate having been enucleated, the microscope proves certain portions to be malignant. Equally certain is it that careful rectal and bimanual examinations will enable a skilled surgeon to recognize prostatic cancer in the great majority of cases, provided that the patient has symptoms which make him seek medical advice. But the symptoms of this disease are even more insidious than are those of prostatic hypertrophy, and it is the undoubted opinion of British urologists that cases of prostatic cancer commonly present themselves when the disease is far too widely spread, metastases in bone frequently being present, to be eradicated by any form of operation.

---

[1] *J. Urol.*, 1945, 53, 185.

Treatment with stilboestrol has therefore been widely welcomed. Claims for the efficacy of this have been exaggerated, but undoubtedly it often gives relief from symptoms and places a temporary check upon the progress of the disease. As for other attempts to arrest the disease, radium treatment is advocated by some but has not generally met with approval. Technically, the implantation of radium into the prostate can be conducted with precision, but unfortunately the passage of the needles breaches the barriers which confine the disease and malignant emboli are not infrequently liberated. Deep *x*-ray therapy by itself has so far not given much help, though it should be used as an aid in certain circumstances; and so when, in spite of stilboestrol dosage, difficulty in micturition becomes important a choice has to be made from other methods available for relief. The passage of bougies, which avails nothing in benign prostatic enlargement, sometimes suffices to improve micturition in cases of cancer. Permanent suprapubic cystostomy is of proved value, provided the operation is properly performed and the patient trained in the management of his apparatus. But perurethral prostatic resection, when practicable, is the method of choice. It is commonly more easy to perform in cancer than in benign enlargement, for the reason that haemorrhage tends to be less. It does not, as has been stated, hasten death by spreading metastases, and it does not usually need to be repeated. Of course none of these procedures delays the fatal issue due to uraemia, which is so often brought about by the involvement of both ureteric orifices in the upward extension of the growth. Young's operation is designed to prevent this, but cases must be found in a state still amenable to radical surgery, and the patient must be prepared to face the possibility of some imperfection in urinary control.

PHYTIC ACID AND CALCIUM DEFICIENCY

Some twenty years ago Mellanby noted that the addition of certain cereals to diets low in calcium led to severe rickets in growing animals, thus confirming the clinical observation, made in Trousseau's day (1865), that diets consisting largely of cereals, particularly oatmeal, predispose to rickets. It has since been shown that this rachitogenic action of cereals is due to the presence of phytic acid (inositolphosphoric acid), which forms an insoluble compound with calcium in the gut, thus preventing its absorption. Not only is calcium precipitated and lost to the body but also the phosphorus in the inositol and some of the iron present in the gut.[1, 2] Phytic acid is widely distributed in foodstuffs, particularly cereals, of which it constitutes from 50 to 70% of the phosphorus. It is therefore easy to understand that a diet mainly of cereals and poor in calcium may cause rickets. Whole-grain flour contains more phytic acid than white flour, and although it contains more calcium and phosphorus than the latter it is an undisputed fact that in the experimental animal it is more rachitogenic. The advocates of the white loaf have therefore argued that flour of high extraction, such as wholemeal or the 85% extraction flour introduced between 1942 and 1944, is undesirable unless fortified with calcium. The objection is largely a theoretical one unless a diet containing much bread and little calcium is consumed. Has it ever been shown that the incidence of rickets is greater in those parts of Europe where whole-grain bread is consumed than in Britain or America, where the bread most favoured is white? Moreover, there is abundant evidence that in whole-grain bread as normally prepared much of the phytic acid is inactivated. When dough is made from flour it is allowed to "rise" for some hours, and Mellanby[3] has shown that the enzyme phytase present in the flour and yeast destroys most of the phytic acid while the dough is rising. This is a practical confirmation of the observation made by Mellanby[4] six years ago that the rachitogenic effect of phytic acid disappears on hydrolysis. It is therefore probable that, under ordinary conditions of baking, brown bread is not appreciably more rachitogenic than white. There are reasons, however, for believing that the rachitogenic properties of oatmeal are retained when it is served on the table. Oatmeal is generally eaten as porridge, and when it is boiled with water the phytase is destroyed before it can inactivate the phytic acid. McCance and Widdowson[5] have also shown that oats contain much less phytase than wheat. Porridge is largely eaten by the lower-income classes, and often with insufficient milk. If it is taken with plenty of milk there is enough calcium in this to offset the rachitogenic action of the phytic acid. It is more than possible that a high consumption of oatmeal with insufficient milk may be associated with rickets in infancy and decalcification in adolescence.

McCance and Widdowson[6] state that when brown bread forms about half the calories of the diet—a very high proportion—calcium absorption is not so good as when an equivalent quantity of white bread is eaten. They recommend the addition of calcium to correct this defect, although Krebs and Mellanby[7] and Cruickshank[8] think that this may not be necessary. What is important is the phytic acid/calcium ratio of the diet as consumed. There is insufficient evidence to prove that brown or high-extraction bread is likely to cause decalcification when eaten as part of a mixed diet containing adequate calcium. When it is eaten in large quantities as part of a diet low in calcium, decalcification can occur. This is particularly true in China and the East, where diets consisting mainly of cereals are thought to be an important contributing factor in the pathogenesis of osteomalacia,[9] which is the adult equivalent of rickets due to calcium deficiency modified by the absence of growth.

CHILDREN WITHOUT HOMES

A special committee of the British Medical Association has prepared a memorandum of evidence for submission to the Interdepartmental Committee on the Care of Homeless Children. The problem of the homeless child and the child separated from its home was examined earlier in the year by a conference of expert practical workers convened by the Women's Group on Public Welfare. Its report,[10] containing seven full-length lectures and notes of discussion, has covered much of the ground, at any rate so far as this country is concerned. As was to be expected, the speakers confirmed and amplified the views set out by the Provisional National Council for Mental Health in its

memorandum on the care of children brought up away from their own homes.[11] Miss L. Rendel, who has done outstanding creative work with the Caldecott Community, estimated the number of homeless children at over 100,000, and declared that little accurate co-ordinated information about their education, treatment, and after-care is available. Many central and local authorities and many voluntary agencies are dealing with them sporadically. Probably none of the many homes considers itself adequate to meet its problems; all suffer from inadequacy of staff both in numbers and in knowledge. Unless the Government establishes some central body, with power to direct and help, confusion may reach a dangerous level. The primary necessity, Miss Rendel held, is that the best method should be sought for each child; schemes must therefore have infinite variety. Any scheme of unification must, she said, include a system of reception or allocation centres to find suitable environments for the children and suggest improvements in existing residential institutions. The adoption system, even under the new Act, leaves much to be desired, and speakers declared that adoption should be arranged only by qualified people and should be far less freely used. Mr. B. E. Astbury, of the Charity Organization Society, regards it as absolutely essential that every unwanted child should become a ward of the State.

The boarding-out of children with foster-parents has definite advantages over other types of care, because it can put the child in a family environment. Children must, however, be placed by skilful, sensible people who can fit the child to the home; supervision must be carried out by people who are able to take an all-round view of the child's life. Miss M. Dyson, of Dr. Barnardo's Homes, laid stress on the psychological testing of foster-home children and the importance of ascertaining the mental defective before he goes out to a family whom he will bitterly disappoint. All workers agree on the paramount importance to a child of home influence. The West Sussex Children's Homes, which are housed in eight cottages and a detached nursery in the midst of fields, give something approaching a real home life, and are especially valuable to children starting out to find their first jobs. Approved schools, at their best, teach boys and girls to become decent men and women and to live with others; they really seem to inspire affection in their charges. In placing children in work vocational guidance is proving more and more valuable, especially if temperament is tested as well as intelligence. Few people realize the great difficulty and importance of after-care for children who have been placed in jobs. Its object, Miss M. Chavasse (also of Dr. Barnardo's) explained, is not merely to keep the children out of prison but to give them the best possible substitute for a parent and a friend who will stick to them through thick and thin.

Staffing in these days is perhaps the most difficult part of the whole problem. Dr. R. E. Lucas, of the Tavistock Clinic, spoke of job analysis, the diagnosis of the individual, and an assessment of his personality trends, but he did not and could not indicate where the candidates were to come from. He did, however, make the important point that to raise the standard for admission to a job does not discourage applicants but attracts a better type of candidate, even if the salary is not raised. He suggested that some central body should conduct a recruiting campaign, and that the various organizations should appoint a matron and a medical psychologist to advise organizations and authorities over a wide area. The training of staff, according to Miss A. A. M. Wilson, who spoke for the Associated Council of Children's Homes, should aim at helping the students to know and understand more about children themselves and society, to deepen their experience of spiritual truth, and to bring to them the importance of presenting to the children the right kind of life, and living it. The Government has recognized the need for concerted action by appointing the Interdepartmental Committee between the Home Office and the Ministry of Health, to which the B.M.A. is offering expert evidence from the medical point of view. The problem of children deprived of a home or parental care is far too urgent to be shelved any longer.

VAGOTOMY FOR PEPTIC ULCER

Since it is generally admitted (1) that most gastro-duodenal ulcers are associated with hypersecretion of gastric juice, (2) that psychological factors are important in exacerbating ulcer symptoms, (3) that peptic ulcers may arise in experimental animals, and sometimes clinically in man after lesions of the vegetative centres in the hypothalamus, and (4) that the vagi are the extrinsic secretory nerves of the stomach, it would seem logical to examine the effect of operative division of the vagi in patients suffering from peptic ulcer. The vagi are accessible where they lie on the oesophagus at its emergence from the thorax into the abdomen, but their arrangement at this level is rather variable; certain gastric branches have already separated, a plexiform arrangement of multiple cords may replace the two main trunks, and operative intervention seldom effects a complete vagal denervation of the stomach. The alternatives are to divide the gastric nerves peripherally as they approach the curvatures, and to divide the main vagal trunks within the chest. Dragstedt and Schafer[1] have adopted the latter method in thirteen patients with duodenal ulcer, one patient with gastric ulcer, and one patient with jejunal ulcer. After extensive resection of the seventh or eighth rib and cartilage on the left side the left lung is mobilized by ligation and division of the inferior pulmonary ligament, and retracted upwards by a round broad-bladed retractor. The pleura over the lower 10 cm. of the oesophagus is opened, and the oesophagus is mobilized and elevated outwards. Both main vagus trunks and all separate nerve cords on the surface of the oesophagus are identified without difficulty, ligated, and divided. The proximal ends of the divided nerves are then sutured to the pleura to prevent regeneration, the oesophagus is replaced in its bed, the pleura is sutured, and the wound is closed without drainage. The patient begins to get up twenty-four hours after operation.

The patient who had suffered from gastric ulcer was apparently entirely cured, as judged by relief of symptoms and disappearance of skiagraphic and gastroscopic signs. The patient with jejunal ulcer, though improved, has continued under medical management. All but one of the patients with duodenal ulcer were improved or cured. Three patients developed signs of gastric stasis after the operation, and one of these proceeded to an acute dilatation of the stomach; all three were relieved by gastro-jejunostomy. This, the only serious disturbance in the physiology of the vagotomized stomach, is doubtless due to the removal of the evacuant vagal function. In all cases the excessive continuous night secretion of gastric juice was much reduced by vagal section. It is not stated whether the patients who were cured or relieved remained symptom-free under normal civilized conditions of diet, environment, and employment, and to what extent they tolerated, after operation, the fatigue, anxiety, overwork, and irregularity of diet which the normal healthy adult expects to support without symptoms of dyspepsia. That the standards of cure approached this exacting criterion, which must be the aim of treatment in gastro-duodenal disease, is suggested by the statement that only one patient remained under medical management. The authors conclude that "the striking improvement in these patients is in harmony with the view that gastro-duodenal ulcer is a psychosomatic disease, and that the central nervous system affects the stomach via the vagi, probably chiefly through greatly augmenting the secretion of gastric juice."

THE ANTINARCOTIC CAMPAIGN IN EGYPT

Sir T. W. Russell Pasha, Director of the Central Narcotics Intelligence Bureau, in his report for 1944 to the Egyptian Government reviews with well-merited satisfaction the achievements of the Narcotics Bureau during the sixteen years of its existence. When the crusade against the illicit traffic was started "the country was in what seemed to be an almost hopeless state of addiction to heroin." The seizure of heroin in 1944 amounted to 1½ grammes, compared with 80,000 grammes in 1929. This "happy immunity" is, however, partly attributable to the wartime closure of Egyptian ports to sea-borne drug traffic, but also in large measure to the work of the League of Nations in securing international control over cultivation and trade in opium as "the basic source of most of the habit-forming drugs." While the heroin problem has diminished, the seizures of hashish have, however, gone up during the last five years to an annual average of 1,688 kilos, against 723 kilos in 1939, and the seizures of opium increased by 40% in 1943. These drugs are smuggled into Egypt through a hundred-mile strip of desert which is constantly crossed by streams of military vehicles whose drivers, of many nationalities, make money by lifting the goods across the frontiers. Most of the hashish seized is grown in the Lebanon and Syria, but opium seized in Palestine after transit through Syria and the Lebanon must have come from outside. The Director is concerned about the future of alkaloid factories in the Balkans and Central Europe as sources of contraband traffic, and has received assurance that Allied control will at once be placed on these avenues of illicit trade as occupation is effected. As to the relative evils of hashish and opium addiction no doubt is entertained that while the former "are harmful the latter are deadly"; moreover, the danger is "that hashish and opium addiction predispose to heroin addiction." While in 1944 some 1,000 acres of cannabis were pulled up and 50 tons of hashish burnt, the bulk of the remaining 30 tons entered the Egyptian market, representing £E6,700,000 in the wholesale. As the report concludes, "the squandering of these vast sums of Egypt's money in smokers' dreams can only be considered a national calamity."

LIGATION OF PATENT DUCTUS

During the last few years the surgery of the heart has made remarkable progress. One of the most interesting developments is ligation of the patent ductus arteriosus. Rae Gilchrist[1] has reported 14 cases, Geoffrey Bourne[2] 11, Terence East[3] 13, and Holmes Sellors[4] 10. Cases of patent ductus arteriosus may be divided into two groups: the infected and the uninfected. In probably about half, and perhaps more, of those patients who die from the defect the ductus is infected.[5] But the chances of cure of an infected case by ligation are good, a survey of the various series showing that about two out of three are saved. There are clear reasons why operation may fail to cure. There is always the possibility that the pulmonary valves, or the aortic and mitral valves, may become attacked. Ligation of a ductus full of clot may fail to close it. The patients are sometimes very ill and there may be infarcts in the lungs. No doubt early diagnosis of infection and prompt treatment offer the best chance of success. Perhaps penicillin will prove to be useful in these cases, for the results of the treatment of early cases of bacterial endocarditis are encouraging; at present there can be little doubt that surgical treatment of an infected ductus should be undertaken as soon as possible.

Patients who have not become infected may have ligation done to protect them from infection, and also from the possibility of heart failure. A patent ductus has a variable effect on growth and development. Some children grow up well and healthy; others are weedy, stunted, and backward; and the ultimate prognosis, apart from the risk of infection, cannot be good, for it is rare to meet with cases after middle age. Apart from this, the presence of such a lesion will debar the owner from life assurance, many avenues of employment will be closed to him, and his life will probably become more and more restricted. To be able to eliminate all these disadvantages with a minimum of risk is certainly desirable. The risks of operation seem to be quite small. Haemorrhage and infection have been recorded, and in some cases ligature appears to have been ineffective; but these technical difficulties should disappear in time. A small effusion may form, a small pneumothorax may be left, or there may be a certain degree of collapse of the lung: these soon clear up with breathing exercises. Children between the ages of 6 and 12 tolerate the operation extremely well. Later on, the enlargement of the pulmonary artery may introduce difficulties and the ductus may be very short; the operation also causes more disturbance. In adults cardiac embarrassment would be an indication for operation. Probably the best time for surgery is soon after the sixth year, when the operative disturbance is relatively slight, and a lesion can be removed which may impair growth and development and incur the grave risk of infection. The immediate benefit in some children may be most striking.

NOBEL PRIZE FOR MEDICINE

It was announced in Stockholm on Oct. 25 that the Nobel Prize for Medicine for 1945 has been awarded jointly to Sir Alexander Fleming, F.R.S., F.R.C.P., F.R.C.S., professor of bacteriology, University of London, at St. Mary's Hospital Medical School; Sir Howard Florey, Ph.D., M.B., F.R.S., professor of pathology in the University of Oxford; and Dr. Ernst Boris Chain, lecturer and demonstrator in chemical pathology in the University of Oxford. This award is made by the Karolinska Institute for the discovery of penicillin and its healing effects. The Institute recognizes Sir Alexander Fleming as the real discoverer of penicillin in 1928, and praises Sir Howard Florey and Dr. Chain for exploiting his discovery by experimenting with its effect upon mice to the advantage of humanity. Penicillin, the announcement says, has rendered mankind one of the greatest services. It was in 1938 that a team of research workers at the Oxford School of Pathology began their investigations on the therapeutic uses of penicillin. The Nobel Prizes are awarded from a fund bequeathed by Alfred Nobel, who died in 1896; no awards were made for the years 1940, 1941, and 1942.

The Council of the Royal College of Surgeons of England is prepared to consider applications from demobilized officers for assistance in the completion of research work on which they have been engaged while serving in the Royal Naval, Army, or Royal Air Force Medical Services.

A NOTE ON DIPHTHERIA INCIDENCE IN CERTAIN EUROPEAN COUNTRIES

BY

G. STUART, O.B.E., M.D.

Health Division, European Regional Office, U.N.R.R.A.

England and Wales

In England and Wales diphtheria morbidity and mortality have alike shown a spectacular decline within recent years. The year 1944 provided the lowest incidence and mortality ever recorded; and this gratifying state of affairs is to be traced to mass immunization of children against diphtheria, which, begun in 1940, has since continued without interruption. Between 1940 and 1943 no fewer than 4,829,115 children under 15 years of age had been immunized—the estimated population of those ages in 1943 having been 8,583,000. Analysis of the returns made for 1943 shows the following rates:

Annual rates of incidence per 1,000 child-years:	
(*a*) In immunized children	1·16
(*b*) In non-immunized children	4·06
Annual rates of death per 1,000 child-years:	
(*a*) In immunized children	0·0104
(*b*) In non-immunized children	0·260

The estimated death rate in 1943 from diphtheria was about 25 times as great among the non-immunized as among the immunized. In the two years 1942 and 1943 the ratio was about 23 to 1.

But England's experience in this respect has not been paralleled by that of many other European countries, certainly not in France, Germany, Belgium, the Netherlands, and Norway. Of all the communicable diseases, diphtheria has shown in those countries by far the greatest increase during the war period; and this increase has been greatest in countries—e.g., the Netherlands and Norway—where the disease had in pre-war years reached the lowest level and where in consequence the proportion of susceptible individuals was highest.

France

In France, despite the proportion of children of school age inoculated against diphtheria with Ramon's diphtheria toxoid, a very considerable incidence was observed each year—an incidence which has become significant since 1941. Thus, whereas the average annual incidence during the 11-year period 1928–38 was 19,371 cases (maximum 23,714 in 1930 and minimum 16,264 in 1936) and the median for the same period was 19,893, the number of cases, which had dropped to 14,019 in 1939 and to 13,568 in 1940, rose steeply to reach 46,539 in 1943—i.e., an increase in the morbidity rate per 100,000 from 32.3 (in 1940) to 110 (in 1943). The first half of 1944 provided 22,179 cases, as against 22,957 in the corresponding 6 months of 1943; thus showing little reduction from the abnormal increase of 1943. During 3 months of the latter half of 1944—from August to October—the number of cases fell to 6,030, as against 10,025 in the same period of 1943. Thus 9 months of 1944 yielded 28,209 cases, as compared with 32,982 in the corresponding 9 months of 1943, and with the median figure of 14,083 for the same period. The 1944 incidence in France has therefore been twice as great as in ordinary years, and the morbidity rate per 100,000 has been 90, as against 110 in 1943 and 32 in 1940.

As regards mortality, the proportion of deaths to cases would appear to have remained unaltered. In this connexion the mortality rates per 100,000 inhabitants of certain French towns during 1938 are of interest:

Town	Mortality Rate per 100,000	Town	Mortality Rate per 100,000
Bordeaux	1·9	Montpellier ..	3·3
Dijon	2·1	Nancy	3·6
Lille	6·5	Nantes	1·0
Lyons	3·2	Paris	2·5
Marseilles	4·7	Saint-Etienne ..	10·0

Greater Germany

In Greater Germany the number of cases in the first 40 weeks of 1944 is stated to have been 204,361, as against 197,831 in the corresponding period of 1943. This increase proves that the incidence, which has been progressively rising since 1939, is continuing on a still higher level. In the 11-year period 1928–38 the annual median was 78,452 for the Altreich, but epidemic peaks had been observed in 1928–9 and in 1935–7. The occurrence in the Altreich of 446,333 cases in the 3-year period 1936–8 had already placed diphtheria among Germany's major public health problems, but the position in the succeeding 5 years was aggravated in the territory by a rise from 143,584 in 1939 to 238,409 in 1943. In Greater Germany between 1939 and 1943 the incidence rose from 174,891 to 196,568 cases. As in other countries, distribution has been unequal; thus whereas the incidence was relatively low in Hamburg, Oldenberg, Bremen, Brandenburg, Württemberg, and Baden, it was high in East Prussia, Saxony, Silesia, Anhalt, Westphalia, and Bavaria.

As regards case mortality, the percentage fatality between 1934 and 1938 was respectively 4.6, 4.7, 3.8, 3.7, and 3.5. In 1939 it was 5%. In 1944 the case mortality rose to over 6%—thus showing an increase of 70% between 1938 and 1944; and it may be confidently asserted that, in view of the very large number of cases under consideration, the increase can scarcely be regarded as accidental.

In the Altreich, morbidity rates have risen during the past 5 years from 180 in 1939 and 174 per 100,000 in 1940 to over 300 in 1943 and 1944; while in Greater Germany the corresponding rates have been respectively 184, 179, and 315 per 100,000.

The severity of the type of diphtheria in Germany is further reflected in the fatality rates per 100,000: (*a*) in the Altreich between 1936 and 1939, and (*b*) in the Grossreich between 1940 and 1944.

Mortality Rates per 100,000 between 1936 and 1944

Altreich		Grossreich	
Year	Rate per 100,000	Year	Rate per 100,000
1936	9·3	1940	9·0
1937	8·4	1941	11·0
1938	8·4	1942	15·5
1939	9·3	1944	18·0

The reason underlying the high morbidity in Germany and its incorporated territories is largely determined by the absence of any nation-wide policy of immunization comparable to that so successfully applied in Great Britain. On the other hand, a large-scale campaign was introduced in the pre-war period in Western Germany, while an increase in diphtheria morbidity and mortality has since led the Reich and Prussian Ministry of the Interior to approve immunization in those parts of Germany particularly affected. Moreover, immunization is compulsory for all youths at the beginning of their Landjahr—i.e., their year of agricultural service.

Belgium

In Belgium, incidence—which had risen alarmingly from 2,419 cases in 1939 (and a yearly median of 2,089 cases) to 16,072 cases in 1943—showed a decline after the first quarter of 1944. As a result the total incidence in the first 11 months of 1944 was but 6,112 cases, as compared with 13,681 in the corresponding period of 1943. The following tabular statement provides figures to illustrate the trend quarter by quarter in 1943 and 1944.

Diphtheria Incidence in Belgium by Quarters, 1943–4

Year	1st Quarter	2nd Quarter	3rd Quarter	4th Quarter (2 months)	Jan. to Nov.
1943 ..	3,085	2,885	3,621	4,090	13,681
1944 ..	3,373	1,398	647	694	6,112

The importance of the diphtheria impact on Belgium will be appreciated from the fact that between 1928 and 1938 the average number of cases annually reported was 2,111, while the average number of deaths from diphtheria was no less than 446 yearly during the same period. The subjoined table shows for the period 1930–8 the number of cases and deaths, morbidity and mortality rates per 100,000 inhabitants, and the percentage of case mortality. Morbidity and mortality rates have been calculated on a population increasing from 8,092,000 in 1930 to 8,386,000 in 1938.

Diphtheria in Belgium, 1930–8

Year	No. of Cases	Morbidity Rate per 100,000	No. of Deaths	Percentage Case Mortality	Mortality Rate per 100,000
1930	2,848	35·2	505	17·7	6·2
1931	2,016	25·0	455	22·0	5·6
1932	2,265	28·0	464	20·4	5·8
1933	2,169	26·2	470	21·2	5·8
1934	2,339	28·2	382	16·3	5·7
1935	1,780	21·4	384	21·5	4·6
1936	1,916	22·8	377	19·6	4·5
1937	2,090	24·8	476	22·8	5·7
1938	2,572	30·7	499	19·4	5·9

In 1940 the incidence rose considerably; in 1941 it was already twice the average (with 4,271 cases); and 1942, with the still higher incidence of 5.464 cases, paved the way for the explosive outburst of 1943, which provided 16,072 cases—an incidence nearly 8 times the average. The year 1944 saw a continuation of epidemic prevalence only until March, since when the curve of the incidence has fallen rapidly. November, with 447 cases, showed an incidence about one-fifth that of Nov., 1943, but one still nearly twice the normal.

It is of interest to compare the mortality of 1921 with that obtaining within recent years; in 1921 there were 884 fatal cases—representing a mortality rate of 11 per 100.000, as against the 6 reported to-day. It is stated that the mortality rate for children beween the ages of 1 and 15 years was 34.6 per 100,000 in 1910, as against 20.3 between 1929 and 1931 and as compared with 15.0 in the Netherlands. In this connexion also the 476 diphtheria deaths in 1937, which represent an overall mortality rate of 5.7 per 100 000, have to be contrasted with the Netherlands rate of 1.4 in the same year.

As regards prophylaxis, immunization with Ramon's antitoxin has been fairly widely attempted, but is not compulsory.

The Netherlands

Caught up in the epidemic wave which swept over Western and Central Europe during 1942 was also Holland, from which country the wave shows even now little sign of receding. In a country where incidence during the 11-year period 1928–38 averaged 3,700 cases annually and deaths from diphtheria 210, the number of cases, which in 1939 had reached the low figure of 1,273 (14.7 per 100.000 inhabitants), totalled 5,501 in 1941, 19,527 in 1942, and 56,603 in 1943—representing morbidity rates per 100,000 of 63.6, 226, and 655. The 1943 incidence was thus 44.5 times greater than that of 1939 and 15 times the 1928–38 annual average. It is somewhat difficult to estimate the 1944 trend of the disease, as statistics are far from complete. The occurrence of 20,669 cases in the first quarter alone, however, showed that the epidemic had reached new heights, the incidence having been nearly twice that of the corresponding quarter of 1943. Moreover, that the incidence continued on this unprecedented high level during the second quarter is proved by the following returns: April (3 weeks), 3,938 cases; May (2 weeks), 2,262 cases; and June (complete), 4,293 cases. It would be safe to assume that the second quarter yielded, therefore, about 14.068 cases, making the first half-year's total 34,737, as against 19.627 in the corresponding half of 1943. July provided 3,674 cases and August (3 weeks) 3,182, as against 2,658 and 3,466 in the complete months of July and August in 1943.

Although figures have not been made available since Aug. 20 it is evident that 1944 has provided an even greater diphtheria problem than did 1943. With some 43,654 cases in the first 8 months and incidence during the remaining 4 reported as being not less than in 1943, it would appear that 1944 constituted the peak year of the war period.

In explanation of the ravages made by diphtheria in the Netherlands it has been advanced that the immunization programme, which in respect of school-children was formerly widespread but not universal, was not carried out during the war years. Thus two-thirds of the children from 6 months to 12 years of age in the liberated areas of Holland have not been immunized against diphtheria. (A new immunization campaign, however, has now been started.)

During the epidemic years it is noteworthy that the case *fatality rate* has not increased—remaining, as in non-epidemic times, somewhere between 4.5 and 6.9%. Thus the case mortality rate in Holland is similar to that in Germany, but much lower than that in Belgium.

The following table shows the distribution of diphtheria in the four provinces of Limburg, Zeeland, Noord Brabant, and Gelderland during the years of occupation.

Diphtheria in Holland, 1940–4

Province	Population	Number of Cases				
		1940	1941	1942	1943	1944
Limburg	653,000	681	2,322	3,699	4,311	1,793*
Zeeland	254,000	9	35	333	965	493†
Noord Brabant ..	1,103,105	436	1,308	2,872	2,798	1,612†
Gelderland ..	993,000	139	515	2,434	5,676	3,578*

* To September. † To August.

In the year 1943, in respect of which complete returns are available, the morbidity rates per 100,000 are thus shown to have varied widely, but in all cases to have been extremely high—viz., Limburg, 660; Gelderland, 572; Zeeland, 380; Noord Brabant, 254.

Norway

Norway in 1939 had but 54 diphtheria cases; in 1943 it had 22,787. Thus with a morbidity rate per 100,000 mounting within 5 years from 1.8 to 760, Norway has earned the unenviable distinction of being the most intensely infected country during the worst diphtheria wave Europe has experienced in 50 years. Now, diphtheria incidence in Norway had been decreasing regularly during the decade immediately before the outbreak of World War II; and, because it was not considered necessary, immunization had not been carried out. But after the German occupation of the country the whole picture changed dramatically, apart from the fact that clinically the disease would not appear to have been more malignant than before, the case mortality still varying between 3.4 and 6.9%. In the autumn of 1941 diphtheria broke out in epidemic form, with the result that by the end of that year 2,611 cases had been reported, as compared with 138 in 1940. In 1942 the disease took heavy toll of the susceptible population, and 8,349 cases were notified—the incidence having been some three times higher in the towns than in the rural areas, and especially high in Stavanger. During this period the extension of diphtheria was mainly from the ports towards the interior and from the south northward. In 1943, when with 22.787 cases the overall morbidity rate of 760 per 100,000 had been reached, the incidence was no less than 3,400 per 100,000 of children under 15 years of age—the highest recorded in Europe during the war. Indeed, the only comparable attack on child life experienced in this war epidemic was in the Netherlands, where during the 3 years between April, 1941, and March, 1944, 102.726 diphtheria cases were reported among a population of 8,640,000, of which about 2,500.000 were under the age of 15 years. From this it emerges that during the 3 years under review as many as 4% of the child population in Holland between 1 and 15 years fell victim to the attack. In Germany the incidence among children under 15 years of age during 1943 was one-half that encountered in Norway in the same year.

After incidence began to rise in so alarming a fashion, active immunization is stated to have been made compulsory for school-children in Oslo and in many other cities, yet in 1942 only 15.000 were reported to have been thus protected. The temporary lack of toxoid was the reason assigned for so unsatisfactory a result of the immunization campaign. In any case, the campaign was launched too late to arrest the outbreak in its early stages.

As regards 1944, statistical data are incomplete. The disease would, however, appear to have declined somewhat, although in the first quarter of the year 4.884 cases were reported, as against 4,391 in the corresponding quarter of 1943. In the second quarter 1944 produced 3,215 cases; 1943 in the same period had 4.017; while the combined incidence of July and August in 1944 totalled but 1,321 cases, as against 3,410 in the corresponding 2 months of 1943. Thus in 1944 between January and August there were 9.440 cases, as compared with 11.908 in the same 8 months of 1943; the incidence, therefore, was still 18 times higher than the median (521).

Observations

From 1941 there has been in Northern and Central Europe an increase in diphtheria incidence unparalleled since control of the disease became possible.

Diphtheria has proved to be the leading epidemic war disease on the European continent, both in morbidity and in mortality.

Only in such countries as have pursued a vigorous immunization campaign over a period of years has a reduced incidence been observed.

The continued high incidence, with a proportionate increase in the number of carriers, places diphtheria high on the list of post-war problems in Germany and the liberated countries of the north and west.

PUBLIC HEALTH'S DEBT TO EXPERIMENTAL RESEARCH

LECTURE BY SIR WILLIAM SAVAGE

The Research Defence Society on Oct. 12 resumed its series of annual Stephen Paget memorial lectures, which had been interrupted by the war. This, the fourteenth, lecture was given by Sir William Savage, lately County M.O.H. for Somerset and a former president of the Society of Medical Officers of Health. He took as his subject "Public Health and its Debt to Experimental Medical Research." The chair was occupied by Lord Hailey, president of the Society.

Sir William began by pointing out that public health was not a pure science, or indeed a science at all; it embraced the application of all scientific knowledge which might be turned to its purposes. The chief contributing sciences to public health had been bacteriology, physiology (including biochemistry), and, to a less extent, chemistry. The development of many sciences, particularly physiology and bacteriology, had depended mainly upon experimental research requiring animal experiments, and many of the striking advances in public health merely reflected this knowledge as applied administratively. The whole of the indebtedness of public health to experimental medical research could not be comprehended in a single lecture; therefore he took some illustrative examples.

Control of Acute Infectious Diseases

Control over acute infectious diseases was rightly placed in the forefront of the work of a medical officer of health. Such control depended for its success upon the application of precise knowledge of causation, methods of dissemination of organisms responsible, control over spread of infection, and application of methods of immunization. Until bacteriologists and epidemiologists had established the factors concerned in this spread satisfactory progress was impossible. This potent weapon of accurate knowledge was largely due to bacteriology, and had been forged by laboratory workers with animal experiment as the necessary tool.

We now know enough to control the majority of infectious diseases, but to apply such knowledge was not always possible, and sometimes not worth while because of complicating social questions such as interference with the liberty of the subject, the reluctance of many persons to respond to preventive measures, and the likelihood that the inconveniences of control would loom larger than the damage resulting from infection.

His first example of a controlled disease was the enteric fevers. Deaths from typhoid and paratyphoid fevers numbered 371 to the million of population in 1871–5, and fell to 67 by 1911, and to 3 in 1939 and 1940. The initial decline was largely due to improved water supplies and sewage disposal. Meanwhile, field investigations and bacteriological studies showed infected shellfish and milk to be important conveyers of infection; but, while the vehicles were recognized, only rarely could the reservoir of infection and the path from reservoir to vehicle be traced. This knowledge presently emerged as the result of direct bacteriological studies which demonstrated that a material proportion of cured cases continued to harbour the typhoid bacillus and became chronic carriers. It thus became clear that, apart from direct contact infection, the chronic carrier was the key to the infection of new cases, though in paratyphoid fever the chronic carrier was often less important as an agent of spread than the symptomless recently infected person. It was also shown that food such as cream and milk was much more to blame than water as a disseminator of infection.

Recently it had been recognized that both typhoid and paratyphoid bacilli were not one and indivisible, but included a number of types to be differentiated by phage typing, thus enabling the association of a particular outbreak with infection from a carrier to be demonstrated with accuracy. Here Sir William Savage referred to the work of Bradley[1] in tracing the relationship of 22 cases, mostly in Buckinghamshire, notified over two years. These proved to be all of phage type D (an uncommon type), and all were directly traced to a milk producer who was a persistent typhoid carrier on a farm in Wiltshire, a hundred miles from the main cases in Buckinghamshire, the vehicle being milk.

Immunization against Diphtheria

Diphtheria illustrated a different point. Here, while there had been a marked decline in case mortality, until quite recently there had been no serious decline in prevalence. The deaths per million over the period 1856–65 were 247, gradually falling to 120 in 1910, to 88 in 1930, and to an average of 66 in 1936–40. The control covered three stages. The first stage was the recognition of the disease as a clinical entity, without any great knowledge as to its spread and with no specific method of treatment. The second stage started in 1894 with the introduction of diphtheria antitoxin and by the recognition that the usual method of spread was from case to case and could partly be controlled by swabbing and by other methods founded on bacteriological knowledge. Antitoxin, imperfectly used as it was at first, dramatically reduced case mortality. In Metropolitan Asylums Board hospitals the case mortality, which had ranged from 33 to 22 in 1890–5, had fallen to between 8.6 and 5.0 in 1920–5, and the greater part of this decline was due to the use of antitoxin; there was still no corresponding reduction in prevalence. The third stage was the introduction of specific immunization. This was introduced in 1926 in the U.S.A. and Canada, but in this country it had been widely practised only during the recent war. Sir William showed a table of the Canadian figures. In 1901 the deaths per 100,000 population were 35.4, and in 1920 they were still 25.7; in 1925 they were 8.1, and fell steadily until in 1940 they stood at 0.3. The incidence, which was as high as 205 per 100,000 population in 1920, was for the years 1938, 1939, and 1940 respectively 6, 4, and 2.

While efficient immunization protected the individual almost completely, statistical evidence of a general reduction in incidence was unlikely until a material proportion of the susceptible (school and pre-school) population—said by some authorities to be 50%, but he believed it to be higher—was protected; so that it was rather early to look for significant reductions in Great Britain, but the available figures were encouraging.

An Uncontrolled Disease

The lecturer's final example was whooping-cough, chosen as an illustration of the extent to which control depends upon having effective tools. Whooping-cough had been notifiable only for the last few years, so that exact figures of prevalence were not to hand; but there was little evidence of any decline in incidence. As a result of much greater care in management the deaths per million had declined from about 500, at which they stood in 1860–90, to below 100 from 1923 onwards. Deaths per million at ages 1 to 5 still remained considerable. The bacterial cause had been known for nearly forty years, but whooping-cough was so difficult to diagnose before spread of infection had taken place that it was doubtful whether control by ordinary measures was practicable. General immunization would not be worth while; on the other hand, immunization of children under 5, and especially under 2, would eliminate nearly all deaths and the bad after-effects. For this purpose a process of immunization was needed which was both effective and easy to operate.

These three diseases—the enteric fevers, diphtheria, and whooping-cough—illustrated contrasts. The first of the three was much reduced by general environmental means, but only up to a point; and continued progress depended upon accurate bacteriological knowledge and its application. Diphtheria responded not at all to measures of general sanitary improvement, and the whole cycle of control, reduction in case mortality, and final elimination turned entirely upon scientific knowledge largely gained from animal experiment. Whooping-cough was not controlled, and offered the prospect of a great reduction in child mortality only when the present valuable work on immunization became administratively practicable on a large scale.

---

Environmental Improvements

How far were the more favourable health statistics due to general improvement in environmental conditions? When the Public Health Act, 1875, was passed, they were so deplorable that the primary need was to eliminate or improve them by purer water supplies, safe drainage, better food control, improved housing, and a higher living standard, all of which paid handsome dividends; but the stimulus to improvement, and to some extent the line the improvement took, were in large part derived from the growth of scientific knowledge, particularly of bacteriology. A study of public health legislation showed it to be recognized that as the grosser conditions were eliminated the dividends earned were reduced, so that further advances were associated with the application of exact knowledge to particular problems. This was well illustrated by two conditions specially susceptible to environmental improvements—namely, tuberculosis, and the group of conditions included under infant and maternal well-being.

The incidence of tuberculosis was much influenced by environmental factors, but problems connected with direct bacterial infection were also of supreme importance. Tuberculosis was influenced by two factors—the resistance of the individual and the invasive properties of the organism. Resistance was fortified by adequate nutrition, prevention of debilitating infections, and other factors, while invasion by the tubercle bacillus was greatly reduced in potency by keeping the dose of infection low. Hence the need for isolation of advanced cases, removal and treatment of active infective cases, and education of patients at home in anti-infective precautions. The decline in tuberculosis mortality was perhaps the most striking statistical fact in relation to public health.

Infantile Mortality

Again, the decline in infantile mortality in recent years was associated with better environment, but not with improvements in general sanitation. It was localized environment which had improved, and the mortality rate might be low even with bad sanitary conditions. There had been no marked decline in infantile mortality until after 1900, and it was quite unaffected by the bettering of the sanitary conditions which took place before then. The protected environment was one which shielded the infant from the various bacterial infections, especially those affecting the gastro-intestinal and respiratory tracts. The way to bring this environment into being was to be deduced directly from bacteriology and experimental research. It was true that the faulty general environment made control more difficult, but it was ancillary only, and its improvement alone was ineffective.

The downward trend of maternal mortality had been in evidence only since 1936, and was attributable to various factors—but, so far as puerperal sepsis was concerned, largely to the use of sulphonamide drugs and to a better knowledge of the bacterial causes and the practicability of excluding infection.

In concluding this part of his lecture Sir William Savage said that future progress in preventive medicine depended upon the collection and use of knowledge as to all factors which affected health. The two main sources for the acquisition of such knowledge were investigations in the sociological field based upon detailed comparative statistics, and, in the second place, the exercise of the experimental method. Both were valuable, and neither could be neglected without loss. The field method, however, had the disadvantage that there were too many variables, while experimental research could be freed from a multiplicity of variables, though it was limited in certain respects.

Control over Food Supplies

In the early days of public health, control over food supplies was based upon the prevention of chemical adulteration, better standards of cleanliness, and the elimination of gross pathological conditions. But it was soon evident that further progress could result only from the application of exact knowledge, much of it bacteriological. Sir William illustrated this by considering the diseases associated with milk and the problem of food-poisoning. About 40% of milking cows were affected with tuberculosis. True, only about 1% were excreting tubercle bacilli into the milk at any one time, but this involved an infection of the milk supply of from 5% to 7%. In 1929, when he compiled his book *The Prevention of Human Tuberculosis of Bovine Origin*, the number of deaths due to bovine tuberculosis was about 2,000 annually; it was now probably from 1,500 to 1,600. A good illustration of the value of experimental research in public health was the relationship of mastitis in cows to human infections. Acute and chronic mastitis was one of the commonest infections of the cow. There was a glaring discrepancy between the prevalence in cows and the rarity of infection in man, and it took him three years, using goats, to work out the relationship. He was able to show that the type of streptococcus which was the ordinary cause of bovine mastitis was harmless to man, and that the infections which caused human disease were associated with implantation of a pathogenic streptococcus of human origin in the cow's udder—a relatively uncommon mishap. He mentioned this as a comparatively clear-cut instance of the value of experimental research in clearing up public health obscurities.

In pre-bacteriological days there was no scientific knowledge of the causes of food contamination, and such scanty control as there was was exercised along wrong lines. The elucidation of the various bacteriological and chemical causes of food-poisoning had been mainly a laboratory affair, and would have been impossible without extensive animal experiments. It was now known that bacterial food-poisoning was not a problem of tainted or incipiently decomposing food, but was due to infection of food with specific organisms, such as the Salmonella group. With this knowledge the reservoirs of such organisms could be studied, as well as the paths by which they passed from the reservoirs to the food vehicles. Armed with these facts, it was possible largely to eliminate this type of food-poisoning. Thus food control, as a result of these investigations, had been removed from empirical guidance based upon the physical senses to a scientific foundation.

Experiments in Nutrition

Only during the last two decades (Sir William continued) had the paramount importance to public health of a sufficiency of basic foods been realized. This had come about along two lines of inquiry. The first was the discovery of vitamins and the recognition of their influence upon the health of man and animals. The basis of this knowledge was prolonged animal experiments. Concurrently with this laboratory work, public health field studies had demonstrated, on the one hand, that many people were not receiving even the minimum daily intake of essential foods, and, on the other hand, that this deficiency manifested itself in the development of pathological conditions such as rickets or simple goitre, and, less patently, in diminished resistance to infection. Field experiments had also proved that what had been regarded as good nutrition was not full nutrition, and that by the addition to the diet of selected foods rich in accessory substances children increased in height and weight and also improved in mental qualities. This optimum nutrition was being translated into administrative action in milk schemes for schools and in the provision of additional milk and accessory foods for expectant and nursing mothers and young children.

In conclusion, Sir William said that our community was now on the threshold of a third phase in the development of preventive medicine. The first phase was the drive towards environmental improvement; the second was largely one of attack on special diseases or conditions. The widening knowledge now permitted the passage of a third phase, which had as its aim the prevention of deviations from health from whatever cause. Such a new orientation implied that a full study of the causation of all diseases was within the scope of preventive medicine. This was an enormous claim which demanded better machinery of investigation, such as reliable morbidity statistics and accurate records of illnesses, close collaboration with medical practitioners, and detailed studies in workshops as well as in homes.

"Augustus found Rome of brick and left it marble. Much of public health is still of brick, but its foundations are well and truly laid. Give us the stones—in the findings of experimental research—and we will turn the structure to dazzling marble."

A vote of thanks to Sir William Savage was carried on the proposition of Prof. A. V. HILL, seconded by Major Gen. H. MARRIAN-PERRY.

TRAINING AND QUALIFICATIONS OF DIETITIANS

MEMORANDUM FROM NUTRITION SOCIETY

In July, 1944, a Special Planning Committee was set up by the Nutrition Society (English Group) to consider and report on the training of persons in charge of the provision of food in institutions, industrial canteens, hospitals, etc. The committee has summarized its findings in the subjoined memorandum, but one of its members (Miss M. Grant) has dissented from paragraph 1 (concerning membership of the British Dietetic Association and registration as medical auxiliaries). The memorandum is published by the Planning Committee with the consent of the committee of the English Group of the Society, but it should not be regarded as necessarily expressing the view of the Nutrition Society. The Planning Committee is of opinion that the present is an appropriate time for the publication of the memorandum and intends that it should serve as a basis for discussion, from which it is hoped useful suggestions for the training of dietitians will emerge. The memorandum is signed by M. Andross, M. C. Broatch, S. J. Cowell, J. C. Drummond, D. Hollingsworth, D. Johnstone, F. Le Gros Clark, A. Lumby, H. E. Magee, J. R. Marrack, H. Masters, and E. R. Smythe.

1. We consider that the description "dietitian" should henceforth be confined to such persons as are suitably qualified for registration as medical auxiliaries. Persons desiring to qualify must hold a Diploma in Dietetics from a university or training college approved by the British Dietetic Association, or alternatively a degree in dietetics if a degree course in the subject approved by the same body is subsequently established in any of the universities.

DEFINITION

2. The term "dietetics" has been variously defined as "The part of medicine which relates to the regulation of diet" (*New English Dictionary*); as "Medical or Hygienic Art relating to diet or food in health and disease" (Webster); as "The study of food in its relation to human needs, health, etc." (*Universal Dictionary*); and as "The interpretation and application of the scientific principles of nutrition in health and disease" (British Dietetic Association). Of these the last appears to us to be the more precise, and we suggest its expansion to read that dietetics is "The interpretation and application of the scientific principles of nutrition to the human subject in health and disease."

3. The terms "dietetics" and "dietetic treatment" seem to have been well established with their modern connotation by the midde of the nineteenth century; but the word "dietitian," though it occurs about the same period, is commonly of more recent usage. There is some doubt as to the correct spelling of the word. We recommend that the customary spelling be retained; and we define a dietitian as one who is qualified as above.

TRAINING

4. While we consider that the diploma course in dietetics (for particulars see Appendix A) has met the needs of dietitians in the past, the profession has widened its field of activity, and we believe that a uniformly high standard of training should now be established. The most desirable way of reaching this standard would be the opening of a university degree course in dietetics. The course should combine the requisite basic scientific training with all the essential practical work. This would bring the training into line with that of dietitians both in the U.S.A. (see Appendix B) and in the Dominions.

5. While we should always recommend such a degree course as generally to be preferred, we are of opinion that there should be another recognized mode of entry such as the diploma course to the profession intended more particularly for persons whose educational careers were interrupted by the war, or who have decided at a more advanced age than usual to take the dietitian's qualification. This arrangement should, however, be regarded as a temporary one, and it should be reviewed as soon as degree courses are in operation in a sufficient number of universities.

6. The diploma course should be open to all students who hold a university degree or professional qualification similar to those required for the present diploma course (see Appendix A).

7. The diversity of the types of preliminary training at present recognized means that the diploma course has to some extent to be adapted to the varied experience of the students entering the training, especially on the practical side of their work. It is desirable that the student should become familiar from the first with the chemical and physiological concepts implicit in the applied science of dietetics; a preliminary training in nursing and institutional management does not provide sufficient opportunity to acquire this basic knowledge. Nevertheless, we are of opinion that some opportunity should be allowed for qualification to those who, already trained in these subjects, show unusual aptitude for dietetic work.

8. The work of a dietitian responsible to a large hospital or a local authority demands high organizing skill and personal adaptability. Many of those who possess such attributes are still without the full dietetic qualification, but naturally we feel that the lack of such qualification stands in the way of their advancement. We trust that it may be possible for the appropriate authorities to offer some financial assistance to enable such of their catering managers and supervisors as seem capable of reaching the diploma standard to take a training. The profession of dietitian will be much enriched by the recruitment of persons who have successfully controlled large-scale kitchen establishments through the searching years of war.

9. We would emphasize that all courses in the subject, whether for a diploma or a degree, should include adequate practical experience in catering institutions and hospitals approved by the British Dietetic Association. The profession should not in our view be open to those who have attained a degree only in the theoretical and experimental aspects of the science. All courses in dietetics should closely relate practice to theory. The practical training of dietitians might well include some instruction in public health, and this instruction should embrace such visits to clinics and to the homes of the people as would enable the student to acquire some knowledge of the social background of the future work of a dietitian.

10. Many newly qualified dietitians will lack the experience that enables them to deal with the complex problems of catering and administration, and they will have no more than a theoretical understanding of educational or hospital etiquette. It is necessary, therefore, that they should, after qualifying, have ample opportunity of service under an experienced professional person. This can be effected only gradually as the posts of catering officers and meal organizers or dietetic advisers come to be filled by qualified persons capable of initiating their assistants in the complexities of their professional duties.

APPOINTMENTS

11. It is important that the status and function of dietitian should be clearly defined; the present position is vague and anomalous. At present there is a fairly widespread tendency to regard purely institutional work—e.g., in hospitals, orphanages, schools, etc.—as the only proper sphere for a dietitian. There is nothing in the definition of dietetics to justify this limitation of function. Food is by far the most important environmental factor which determines health, and the dietitian should in our view assume her* due place as a public health

---

* It is clear to the Committee that the dietitian of the future may be a man or woman, but for the purpose of this memorandum the feminine has been used.

official. In this capacity she can exert the maximum influence on the community.

12. The medical officer of health as the person responsible for the health of the inhabitants within his area should have on his staff an experienced adviser in dietetics, just as he has special officers to advise him on sanitation, food inspection, and various branches of medicine. A post of this nature would be one for a senior dietitian, and would probably rank as among the highest in the profession. The functions of such an officer would be broadly to advise the M.O.H. on all dietetic matters falling within his sphere: diets in hospital, orphanages, and other institutions controlled by the local authority, school meals, advice on diet to mothers in clinics, and educational work. Such educational work might well include co-operation with those responsible for the teaching of nutrition in schools, welfare centres, and advice bureaux. In addition, the dietitian would be expected to play an appropriate part in the conduct of dietary surveys and other nutritional investigations. Depending on the size of the area the officer would have working under her one or more junior dietitians to whom she would delegate her detailed work. It might also be found convenient for the dietitians of the local authority or voluntary hospitals to collaborate in such a way to ensure expert advice on catering and dietetics to any institution requiring it within the area. In this way the needs for such advice of small hospitals and other institutions—e.g., orphanages and boarding schools—could be most conveniently met. Other desirable fields for collaboration are in educational work and nutritional surveys. Such diversity of function would prevent staleness and improve efficiency.

13. Every hospital of about 150 beds or more should have its qualified dietitian responsible only to the medical superintendent or his equivalent in a voluntary hospital. Large hospitals of about five hundred beds or more would require a number of junior dietitians as well as a senior one. (See Ministry of Health Circular 44/45 and *Memorandum on Hospital Diet* issued by King Edward's Hospital Fund for London.)

14. It is almost certain, too, that senior advisory posts will become available in the health and education departments of the Government, and some of the larger food and drug manufacturing firms will probably require dietitians for advice and research.

15. It is obvious that, if only a proportion of these posts were filled by qualified dietitians, many more dietitians will be required. The membership of the British Dietetic Association is at present over three hundred; many of these are registered as medicial auxiliaries. About a quarter of the members are not in practice.

ESTABLISHMENT OF THE PROFESSION

16. We are aware that the profession should be protected, as far as possible, from the competition of unqualified persons. In the case of other classes of medical auxiliaries, working for the most part under the direction of medical practitioners, this measure of protection is more or less assured. The dietitian may not, however, come into immediate contact with a patient, and for that and other reasons her position is by no means so clearly defined. We stated above the various types of employment we think might be suitably filled by qualified dietitians. It will be necessary to convince the employing bodies that it is in their own interest to seek the services of fully qualified persons.

17. It is desirable, finally, to assure the status of dietitians in local government or hospital employment. The dietitian should be given full responsibility for the work of her department. When employed by a local authority she should be responsible through the appropriate senior officer to the health and education committees. In hospital practice she should be responsible to the secretary or medical superintendent, and should be a member of a catering committee representing those concerned with hospital feeding. In many hospitals the position of the dietitian is not clearly defined in relation to the matron's sphere of control, while she may have little or no contact with the medical staff. If she and her assistant dietitians are to have opportunity of advising and directing in ward feeding, outpatient departments, schools, day nurseries, etc., they must have unquestioned right of access to the chief administrative officer concerned.

Appendix A

Diploma Course (recognized by the British Dietetic Association at present time, June, 1945)

The Diploma Course in Dietetics consists of two parts: a theoretical study of nutrition, followed by a practical course, which must be closely allied to the theoretical work and taken in a hospital recognized by the British Dietetic Association. There are at present four institutions recognized by the British Dietetic Association at which students may be awarded a diploma in dietetics. The length of the course varies from 12 months to 18 months; this time includes the theoretical training and the 6 months' practical work. Students are advised to take a further 3 months' training in large-scale catering in the general kitchen of a hospital or in a canteen.

The Diploma Course is open to students who have one of the following qualifications: (1) University Degree in one of the following: (*a*) household and social science; (*b*) domestic science; (*c*) pure science, including physiology and chemistry and followed by at least three months' concentrated cookery training in an institution approved by the British Dietetic Association. (2) State Registration in Nursing. (Extra training in physiology, chemistry, and cookery may be necessary.) (3) Teachers' Diploma in Domestic Science. (Extra training in physiology and chemistry may be necessary.) (4) Institutional Management Diploma after at least two years' training at a recognized college of domestic science. Such students must hold the School Leaving Certificate or equivalent qualification. (Extra training in physiology and chemistry may be necessary.)

Appendix B

Requirements for Membership of the American Dietetic Association

A. ACADEMIC

1. Either a bachelor's degree from an accredited college or university with the following distribution of courses and hours until Aug. 31, 1944 (academic requirements were raised after Sept. 1, 1944):

Subject	Approved Course Graduates	Experienced Applicants	
		Foods and Nutrition	Institution Management
	(Minimum Semester Hours)		
Chemistry (including inorganic, organic, and physiological. Food chemistry may replace physiological for institution management majors)	12	12	12
Biology (including human physiology and bacteriology)	6	6	6
Social sciences (selected from at least two of the following: psychology, sociology, economics)	9	6	6
Education	3	0	0
Food preparation	6	6	6
Nutrition (including an advanced course)	6	6	3
Institution economics	6	0	6

2. Or a bachelor's degree from an accredited college or university followed by courses to complete the above outline. Five semester credits in nutrition or allied fields must have been secured within seven years of the date of application, except in cases where experience is of a type acceptable to the membership committee as a substitute.

B. EXPERIENCE

The following experience is required in addition to the above college work: Either satisfactory completion of a course for student dietitians approved by the association or two years of successful experience in a position involving responsibility which seems to the membership committee to be the equivalent of such a course. The committee will consider the following types of experience: (*a*) Hospital—this must have included main kitchen supervision, diet therapy, and teaching. (*b*) College teaching in the fields of foods and nutrition or institution management. (*c*) Management of school lunch-room, residence hall, etc. (*d*) Nutrition work with a social service or public health agency. (*e*) Commercial work of a type satisfactory to the membership committee.

At least one year of this experience shall have been within seven years of the date of application.

BRITISH SURGEONS' VISIT TO PARIS

Some months ago the President of the Royal College of Surgeons of England received an official invitation from Prof. Bazy, of the Académie de Chirurgie, asking him and some of his colleagues to attend their first post-war meeting in October, 1945. Accordingly three members of the Council of the Royal College of Surgeons and three Fellows of the Association of Surgeons of Great Britain and Ireland went to Paris on Oct. 7. After years of oppressive occupation the first official meeting of a professional body with the distinguished traditions of the Académie Française de Chirurgie, and under the presidency of Prof. Monchet, could not fail to be impressive. More impressive still was the warmth and friendliness of our welcome, which showed beyond any doubt that this was a genuine expression of feeling coming straight from the heart of our colleagues, and no mere official gesture.

Mr. Max Page (Vice-President of the Royal College of Surgeons) brought official greetings, and presented the president of the Academy with a book of photographs of the Royal College of Surgeons soon after it had been bombed, and he was complimented by an invitation to take the chair at the first scientific session. Later we were given a reception by Prof. Monchet, and were entertained to dinner by Prof. Bazy. On the second day a reception was given by the British Ambassador, and a dinner by Prof. Hartman, the doyen of French and perhaps of European surgeons. A group of Belgian surgeons also gave us an unforgettable luncheon party, and their friendliness well matched the rest of our reception. The significance of this welcome must be seen against the background of Paris as it is to-day. Outwardly, in the warm autumn sunshine, no fantasy could excel its beauty, but daily life for the Parisians is extremely difficult, and we who have our needs provided, albeit in a dull pedestrian way, have little idea of their daily hardships.

We were able to see enough to prove that French surgery and French thought have not been either stagnant or sterile, and it is to be hoped that soon facilities will be available for close co-operation and more intimate personal intercourse. It is for professional bodies and individuals to make history a creative and fruitful process. At the moment this cannot be done without official help. Great Britain is committed to the role of a Continental Power, and for us France is the gateway to Europe. Professional contacts cannot determine policy, but they can make policy easy; it is therefore not unsuitable that in a professional journal we should ask for more facilities for easy and intimate contact with our colleagues in Western Europe.

H. W. S. W.

TUBERCULOSIS IN WAR AND PEACE

Prof. Charles Cameron, in his inaugural lecture as professor of tuberculosis in the University of Edinburgh, began by urging that the public should not be lulled into an illusion of security by falling death figures. Tuberculosis either killed quickly or, having lost the first round, sparred warily with its victim, and the next few years would show how the struggle would go for those who had lately swelled the notification lists. Great Britain had inherited a problem aggravated by years of war.

Scottish Figures

Quoting the main figures for Scotland Prof. Cameron said that deaths from tuberculosis rose from 3,431 in 1938 to 4,175 in 1941; they fell to 3,995 in 1942 and to 3,959 in 1943. On analysis of the age periods of those deaths, the main rise was found to be in children under 5 years of age and in young adults from 15 to 25. Turning to notification, progressive increases were found throughout the same years, but they were almost entirely in pulmonary tuberculosis, the 1943 figures for which were 54% above the 1938 level. The peak of the deaths was reached in 1941, but the peak of notifications had yet to be reached, and tuberculosis was still increasing in the community. Another point brought out by the figures for Scotland was that deaths in 1943 from non-pulmonary forms of the disease (which virtually meant disseminated tuberculosis) were for young women 42%, and for young men 34%, above the pre-war level. Prof. Cameron shared the belief that many or most of those young people were succumbing to late primary infections, but in the absence of exact knowledge of the spread of infection in age groups and areas such statements could not be substantiated.

Detection and Responsibility

Speaking of the schemes of mass miniature radiography, Prof. Cameron said that it had been estimated that in the United Kingdom there were probably 15,000 young adults suffering from unsuspected lung tuberculosis of an early symptomless type. To discover them the whole young adult population must be examined, and the examination must be repeated at intervals. Detection of these cases implied big social responsibilities, which local authorities and Government alike must be prepared to accept. Whether the care of the tuberculous should be put on a national basis was a point needing careful consideration. The disease during the past thirty years had passed into the hands of local authorities and their whole-time employees. Most patients had no alternative to local authority treatment, and the authorities must face the question whether they were fulfilling their responsibilities to those people.

Lastly, Prof. Cameron declared that the milk supply of the future must come from sources above suspicion or the milk must be treated by efficiently controlled pasteurization before it reached the consumer. There ought to be no compromise with an infection which was readily preventable.

RECOGNITION OF CIVILIAN BRAVERY

The *London Gazette* has announced the appointment as M.B.E. (Civil Division) of Mrs. Flora Livingstone Macdonald, M.B., Ch.B., of Aros, Mull, and the award of the B.E.M. (Civil Division) to Messrs. A. Cattanach, D. Ross, and W. Walker. The citation reads as follows:

> An aircraft crashed near the summit of Ben Talaidh, Mull, in very bad flying weather: The aircraft struck the mountain obliquely, at about 2,300 feet, slid downwards some 300 feet, and came to rest on snow in a highly precarious position. Any disturbance of its balance would have caused it to crash into a rocky gorge. There were eight occupants of the machine. One was thrown out at the high level and killed, another was crushed under the aircraft, a third was injured dangerously and died during the rescue work. One injured passenger managed to get down to a cottage to give particulars. The remaining four occupants were all seriously injured and unable to help themselves. Distress signals were sent up and rescue parties were organized. Cattanach was the leader of one party. Snow and ice lay everywhere, with deep drifts. The river was in flood and the banks treacherous. Dr. Macdonald's leg was cut in the ascent, and at one time she was waist deep in icy water and had to be pulled out. When they reached the aircraft she gave first aid to the injured, and the others searched for one of the occupants of the aircraft who was missing. Another search party with stretchers set out, but having no knowledge of the whereabouts of the aircraft they returned. Cattanach and Walker, who had seen their lights, went down the hill to lead the party to the scene of the crash. The stretcher party were now becoming exhausted, and Cattanach and Walker, who were leading them, did most of the heavy work with the stretchers. It had become known that one body lay where the crash first occurred. Ross had tried this climb, up a very steep and dangerous face, but failed in the darkness. A further effort was made in daylight by Walker and Ross, who climbed up successfully, reached the body, and brought it down. By the determination of the rescue parties four lives were saved. In particular Cattanach, Ross, Walker, and Dr. Macdonald displayed courage and endurance of the highest order.

Reginald Norman Macdonald, L.R.C.P.&S.Ed., of Aros, Mull, has been commended for brave conduct when an aircraft crashed.

RÖNTGEN COMMEMORATION IN LONDON

To commemorate the 50th anniversary of the discovery of *x* rays by Wilhelm Conrad Röntgen on Nov. 8, 1895, a series of meetings will be held next week in London at the Royal Society, the Royal Society of Medicine, the Royal Institution, and the Institution of Electrical Engineers. The programme has been planned jointly by a number of societies interested in the medical, scientific, and industrial aspects of *x* rays. Attendance at the inaugural meeting in the rooms of the Royal Society on the morning of Thursday, Nov. 8, will be by invitation only. At the Royal Society of Medicine on Nov. 8 at 4.45 p.m., with Lord Horder in the chair, four short addresses will be given by Dr. R. E. Roberts, Dr. James Brailsford, Prof. F. L. Hopwood, and Mr. Cuthbert Andrews. All the participating societies will hold a joint meeting at the Phoenix Theatre, Charing Cross Road, at 3.30 p.m. on Nov. 9, with Sir Henry Dale, P.R.S., in the chair, when Sir Lawrence Bragg, F.R.S., will give an address on the scientific consequences of Röntgen's discovery of *x* rays. On the morning of the same day Drs. A. E. Barclay and N. S. Finzi will read papers at a medical meeting at the R.S.M., and on Nov. 10 at 2 p.m. at the Institution of Electrical Engineers, with Dr. Russell J. Reynolds in the chair, Mr. H. T. Ferrier will give an address on postgraduate education in medical radiography. A small exhibition of historical items will be held at the British Institute of Radiology, 32, Welbeck Street, W., on Nov. 8, 9, and 10, from 10 a.m. to 6 p.m. Other meetings will be devoted to the applications of *x* rays to physics and chemistry, and to industrial radiology and *x*-ray analysis and equipment.

Reports of Societies

PSYCHIATRIC LESSONS FROM ACTIVE SERVICE

In his presidential address to the Section of Psychiatry of the Royal Society of Medicine on Oct. 9, Dr. G. W. B. JAMES gave a review of lessons learned from military service and suggested ways in which those lessons might influence the future of psychiatry. He counted himself fortunate to be a member of a generation which had survived two major wars. It had meant that nearly ten years of his professional life had been spent in the Army, almost seven of them on active service over-seas. He made grateful acknowledgment of the debt he owed in his own development to the years spent in the Army Medical Service.

The Psychiatric Casualty

After dealing with some aspects of group formation and the knowledge to be derived from a close study of groups of men, Dr. James remarked that in making contact with doctors from all over the Empire in the Middle East Force he had found them, with few exceptions, bewildered by the psychiatric casualty and unable at first to deal with it on active service. He showed a table giving the psychiatric casualties expressed as incidence per 1,000 of the Middle East Force. For all troops they numbered 24.0 in 1941, and 21.2 in 1942, whereas the corresponding figures for battle casualties were 36.7 and 31.1 respectively, for malaria 19.5 and 29.1, and for dysentery 28.9 and 33.3.

"This considerable section of casualties was often looked upon with distaste. It would appear as if the medical training of the Empire's doctors had resulted in an almost obsessional avoidance of the life situation of their patients. Immediate simple therapy in the field tended to be replaced by a frantic testing for allergies, searching for septic foci, an earnest use of x rays to discover the sources of hidden troubles; as a last resort search was made for a nomenclature decently to veil the emotions and other mysteries which might get the casualty into the hands of that less reputable practitioner—the psychiatrist. The practical result of this odd dislike of psychiatry on the part of so many doctors is too often a failure to recognize and handle adequately the recent psychiatric breakdown, whether in war or peace."

The rift between general medicine and psychiatry must not be allowed to widen. Must psychiatry remain a specialty apart? He believed that it was for general medicine to absorb and integrate within itself the principles psychiatry had to teach, while psychiatrists in turn must show their ability and eagerness to absorb the lessons of modern medical advances. The rift might be partly healed by the physical methods of treatment which had been introduced into psychiatry during the last thirty years—malaria in paresis, the insulin therapies, electric convulsive therapy, continuous narcosis, prefrontal leucotomy, and the narco-analysis which had proved so useful in rapid abreaction techniques. These were such effective weapons for the early attack on certain psychiatric conditions that the methods should be made widely familiar to a greater circle of students and doctors. Again, in order to secure facilities for a more extensive psychiatric service the future general hospital must include beds for psychiatry. Properly chosen psychiatric patients were no more trouble than the average medical case, and often gave to therapists an encouragement which could not be exceeded in medical or surgical wards.

Restatement of Terms

Some of the terms in psychiatry were used without sufficient discrimination. "Schizophrenia" was one example, and others were "anxiety neurosis" and "anxiety state," which seemed to be supplanting the old "neurasthenia" as a convenient portmanteau term for everything from alcoholism to senility. During seventeen months in the Middle East 530 cases of psychosis needed evacuation, and 80% of these left the command as cases of schizophrenia, whereas the admission rate for schizophrenia to civil mental hospitals was roughly 16 to 19% of all cases—a figure which included women as well as men. Why did schizophrenia figure so largely in military psychiatry? He was convinced that it was not always fair to the soldier to assume that the stresses of war were never the direct cause of psychotic breakdown. He had seen instances of classical schizophrenic breakdown resulting apparently from battle stress of one kind or another, occurring among men of good type, with good family and personal records. Many men arrived from oversea theatres with the label "schizophrenia"; they were symptom-free, but had a dossier which justified the diagnosis. Some had been suffering from infective conditions, others might have been unusual hysterics, but some might fairly be said to have suffered from an acute schizophrenic episode, the direct result of war service.

Another table shown by Dr. James gave the percentage incidence by units of a sample of 3,724 psychiatric casualties among British troops in the Middle East Force during a period in 1942–3. The casualties in the infantry were 22% of the total of psychiatric casualties, those in the artillery 20%, but those in the service units (the R.A.S.C., R.A.M.C., R.E.M.E., etc.) were 32%, seeming to suggest that the heaviest casualties were experienced in these services and that a smaller incidence fell on the fighting man.

Effects of Battle

Dr. James concluded his address with a discussion of the effects of battle. It was true in general to say that no soldier was quite the same after battle experience. This was the psychiatrist's first problem—the acute battle crisis in which even the trained soldier might regress to the levels of childhood. The second problem of battle was that relating to long campaigns. In his experience it was not possible for soldiers to make an infinite number of calls upon resolution and endurance. The problem of exhaustion was one of the most urgent psychiatric emergencies of war. Battle conditions, nevertheless, were relatively minor factors in the aetiology of psychiatric casualties in the Middle East. The greater number resulted from lack of adequate selection or from the harassing anxieties of separation, domestic and marital worries, climatic conditions, uncertainties, tropical illness, and impropr placement and employment.

The lesson to be learned was the need for a carefully planned organization for assessment, rapid treatment, convalescence and rehabilitation. Understanding approach and immediate sedation was the principal need of the front line. Psychiatric first aid was as urgent as surgical first aid and ought not to require specialist help. The setting up of a new convalescent depot with 200 beds allotted to a psychiatric specialist during the heavy desert fighting of 1942 showed that about 90% of the men breaking in battle could be restored to a good standard of stability, though only a fairly constant 30% returned satisfactorily to combatant duties.

RESPONSIBILITY FOR ACCIDENTS IN RADIOLOGICAL DEPARTMENTS

In his address from the chair of the Section of Radiology of the Royal Society of Medicine on Oct. 19 Dr. W. M. LEVITT, the incoming president, who is forsaking medical practice for the legal profession, discussed the responsibility for accidents in radiological departments.

The incidence of accidents in x-ray work in this country, he said, was low; nevertheless, the total number of cases was not small, and he had himself seen in consultation or for expert opinion a number of injuries due to electrical accidents and x-ray burns in patients and staff. A small proportion resulted from over-exposure in radiodiagnostic work, but by far the larger number were sustained as a result of x-ray or radium treatment. Inevitably in the future large departments would be established in institutions where there was no previous knowledge of radiotherapy, and these would be under the control of bodies with no idea of the special problems they presented.

Dr. Levitt first considered the respective responsibilities of hospital authorities, radiologists, and radiographers. Before 1942 the law was based on the well-known decision in Hillier *v.* St. Bartholomew's Hospital (1909) that the contract of the governors of a public hospital with a patient undergoing surgical operation or examination was only to supply a competent hospital staff and nurses, with proper apparatus and appliances, and unless it was shown that they had failed in this duty they were not responsible for injury caused to the patient by negligence of the hospital staff. There was one qualification to this, that the hospital was responsible for the negligence of the staff in ministerial matters—that is, matters outside their professional duties. For example, if a nurse scalded a patient by spilling a cup of tea over him, the occasion of the act being outside her nursing duties, the hospital might be judged liable, but if she scalded him by the negligent application of a hot-water bottle after an operation presumably no responsibility would lie with the hospital.

The case of Gold *v.* Essex County Council (1942), however, had altered the situation. In this case a competent and qualified radiographer in applying Grenz rays according to a prescription had caused injury by failing to screen the patient's face with the proper screening material which was available. The Court of Appeal in this case laid down certain important principles which now governed the law in the matter. The legal principles were that one who employed a servant was liable to another person if the servant within the scope of his employment did an act so negligently as to injure that person, and that principle applied even though the work was of a skilled and technical character of which the employer himself was ignorant. The liability of the master for the negligent act of the servant would exist although at the time the servant was by direction of the master under the control of a third party. One of the Lord Justices in this case distinguished between a "contract of service" and a "contract for services"; under the first the employee worked under instructions either from the employer or from some person appointed by him, and under the second he was not subject to such control in carrying out his service. It was not unknown in public authority hospitals for the medical superintendent to exercise overriding powers—as, for example, on the ground of economy to cancel a prescription given by a subordinate officer. A medical superintendent might possibly limit the number or extent of the radiodiagnostic investigations in a given case. Such powers necessarily made the medical officer's contract "a contract of service," and not a "contract for services," and threw the burden of responsibility for his acts upon the hospital.

Common-law Duties of Hospital

What were the duties which the law imposed on hospital authorities for the safety of patients and staff? Every conceivable accident that could occur to a member of the staff in the radiological department now came within the Workmen's Compensation Act, even though the employee had been careless of his own safety. In considering the duties imposed on a hospital for the safety of the radiological department—which department differed from most others in that it depended for its operation on potentially dangerous machinery—a House of Lords decision in 1938 laid it down that the duties of the employer were threefold: to provide a competent staff, to provide proper and safe plant and appliances, and to provide a proper system of conducting the work and efficient supervision of the work. The House of Lords also held that these responsibilities could not be delegated. The special meaning of "delegation" made it appear that even though the employer had taken every possible care to ensure the competence of any person to whom he delegated responsibilities, that would be no defence if the apparatus was inadequate or the system of working defective.

It was in considering the radiographer, and especially the radiotherapy technician, that difficulty began. Was the qualified radiographer necessarily qualified to act as a radiotherapy technician? The possession of a radiographer's qualification was no evidence at all of competence as a radiotherapy technician. Many important hospitals employed carefully selected nurses as radiotherapy technicians, giving them the technical training required. Were these hospitals to be in a less favourable position than those which employed a qualified radiographer? Yet many hospitals felt that they must protect themselves by employing only technically qualified radiographers, with the result that people who had acquired radiotherapy technique and experience were lost to the service. It was the radiologist alone who was capable of judging the competence of a radiographer or a radiotherapy technician.

It was the duty of the hospital also to provide a safe system of working. A safe system had two main constituents: (1) adequate protection against dangers and regular inspection and checking of the department; and (2) the framing of such rules as were necessary to ensure minimum exposure. A radiotherapy department required the regular and frequent attendance of a physicist. The common-law duties of the hospital, therefore, were to provide an adequate staff appointed with due care, safe and efficient apparatus, and a safe system of working with due supervision, which, in the case of a radiotherapy department, meant the employment of the services of a physicist, and these duties could not be delegated; they were the strict liability of the hospital throughout.

The Manufacturer's Share

Dr. Levitt finally mentioned the liability of the manufacturer and repairer of apparatus. The law was that when a manufacturer sold his product in such a manner as to indicate that it was intended to reach the consumer in the form in which it had left him, with no reasonable possibility of intermediate examination, the manufacturer was responsible for its reasonable safety on arriving at its destination. In the radiological field the supplier of *x*-ray apparatus which was defective would be liable. Many years ago, Dr. Levitt said, he had had delivered to him a deep-therapy machine from a well-known manufacturer. All measurements were carried out by the manufacturer and it was passed as satisfactory. By chance, just before he used it on a patient, he decided to make some measurements himself, and a skiagram showed that the shadow at the periphery was seven times as dense as at the centre. Further examination and calculation proved that the filter supplied was nearly one centimetre less in diameter than the beam.

SYNERGIC ACTION OF PENICILLIN AND SULPHATHIAZOLE

At a meeting of the Section of Pathology of the Royal Academy of Medicine in Ireland Dr. J. W. **Bigger** read a paper on the synergic action of penicillin and sulphathiazole on *Bact. typhosum*. By using broth from which antagonizing substances had been removed by the method of Harper and Cawson he had found that sulphathiazole in a concentration of 10 mg. per 100 c.cm. had a considerable inhibitory effect upon the growth of small inocula of typhoid bacilli. With large inocula it was almost without effect. Penicillin in a concentration of 9 units per c.cm. and less had some inhibitory effect, even on large inocula. The combination of sulphathiazole and penicillin was not only inhibitory but bactericidal: 4 units per c.cm. of penicillin and 10 mg. per 100 c.cm. of sulphathiazole sterilized broth containing 70,000 typhoid bacilli per c.cm.; penicillin, 1 unit per c.cm., and sulphathiazole, 10 mg. per 100 c.cm., sterilized broth containing 7,000 typhoid bacilli per c.cm. He outlined a scheme for trial in clinical cases.

In the course of a Chadwick Lecture entitled "Health Education, its Problems and Methods," given on Oct. 30 at the Livingstone Hall, Westminster, Dr. Walter P. Kennedy said that health education to-day had developed from hygiene and preventive medicine by emphasizing the promotion of health rather than the prevention of disease. This positive point of view was best understood by applying the methods of dynamic logic or by a statistical treatment of the components of health. By attention to the factors which made up health, improvement could be obtained even in those who would say they were healthy. Once the true meaning of health had been grasped it must be regarded from the holistic point of view. An evaluating survey of the methods of health propaganda and teaching had still to be made. Dr. Kennedy stressed three desirable developments: provision of more "workshops of health"—i.e., swimming baths, gymnasia, and the like, especially in small centres of population; the training of more teachers in biological sciences; and the greater co-ordination of the Churches with the pursuit of national health aims. His general thesis was that no health education could be complete unless it included in its ambit the physical, mental, and moral activities of man.

The rapid strides made since the end of the European war in adapting the plastic "perspex" to peacetime uses were seen at an exhibition in Birmingham recently arranged for the purpose by I.C.I. Already a wide range of commercial articles are being produced, but the only medical items shown among the main exhibits were instruments demonstrating the "piping of light through curved perspex," which could be sterilized in boiling water. The use of "perspex" in orthopaedics has been described more than once in these columns.

Correspondence

Galvanic Stimulation of Denervated Muscle

SIR,—The communications of Fl. Lieut. E. C. S. Jackson and Prof. H. J. Seddon and of Dr. R. E. M. Bowden (Oct. 13, pp. 485 and 487) have so much in common that they may be discussed together. In each of these papers evidence is adduced to show that the galvanic stimulation of denervated muscle tends to limit its atrophy, and this is in accordance with expectation. Upon this conclusion there is based the important assumption that galvanic stimulation is of high clinical value in promoting a good recovery; this assumption, however, is unsupported by direct evidence, either clinical or experimental. For example, in the cases of ulnar paralysis (Jackson and Seddon) there is nothing to show that the functional results were better in the galvanically treated cases than in the cases not so treated. Similarly, in the experimental rabbits (Bowden) there is no evidence that recovery of the galvanically treated limbs took place more rapidly and completely than in those not so treated.

If galvanic stimulation possessed any definite clinical value it might certainly be expected that this would have been noticed by experienced orthopaedic surgeons; yet there is no decided body of opinion on the subject. The general opinion appears to be that the requisites for success in nerve suture are good apposition of the axons followed by judicious after-treatment, the value of electrical treatment being left in doubt. It is certain that good results may be obtained in the absence of galvanic stimulation, either before or after operation.

It is a question that requires careful consideration whether galvanic stimulation may sometimes serve to maintain the muscles at the cost of the regeneration of the nerve, and may thus do more harm than good. This possibility is raised by the observation that the interruption of galvanic treatment has occasionally been followed by an obvious improvement in the rate of recovery. As a theoretical consideration, it is possible that the katabolic activity induced by continual galvanic stimulation may impair the anabolic activity necessary for the slow and difficult regeneration of the nerve. At a certain stage physiological rest may be the best adjunct to recovery, being gradually replaced by voluntary movements as regeneration occurs. To make a somewhat wide comparison, the frequent dressing of surgical wounds was formerly thought to be advantageous, but it is now known that they often do better if they are left alone.

The present aggregation of nerve lesions may afford the opportunity of comparing the functional results in groups of cases treated with and without galvanic stimulation. Direct clinical evidence of this kind would be a more reliable guide to practice than deductions from histological appearances.—I am, etc.,

Sheffield. R. G. ABERCROMBIE.

Morphine as Prophylactic against Ileus

SIR,—The suggestion made by Mr. J. T. Chesterman and Dr. W. J. Sheehan (Oct. 20, p. 528) that morphine can be used as a prophylactic against paralytic ileus is of great interest to the pharmacologist. When a dog is given morphine preparatory to a general anaesthetic it is usual for the dog to pass loose faeces within about 20 minutes of the injection. This I have always supposed to be due to stimulation of the vagus centre in the medulla, for there is a slowing of the pulse rate and often the dog vomits. Simultaneous stimulation of the vagal and vomiting centres is, of course, a common phenomenon. Presumably the beneficial effect of morphine on paralytic ileus is due to this early action, which leads to an increased discharge of motor impulses to the intestines.

The later effects of morphine on intestinal movements are, however, different. Magnus showed in 1908 that morphine delays the passage of a bismuth meal through the intestinal canal of a dog. Whereas in a control observation the meal was seen to enter the colon three hours after it was taken, after morphine the meal did not enter before 12 hours had elapsed. The dose given was very large—0.1 grain per kg., equivalent to 6 grains for a man. I imagine, however, that Mr. Chesterman and Dr. Sheehan would agree that in some subjects at least the ordinary therapeutic dose of morphine has a constipating effect. (See, for example, A. J. Clark's *Applied Pharmacology*, seventh edition, p. 342: "All observers agree that these drugs [morphine and opium] cause a great delay in the passage of the gut contents through the alimentary canal, and there is no doubt that this delay is chiefly caused by contraction of the pyloric and ileo-colic sphincter. Small quantities of morphine frequently cause increase in the peristaltic activity of the gut, and the observers who have studied its action most fully consider that great individual variation in reaction occurs.")

In view of these two opposed actions of morphine, what conclusion are we to draw from the figures given by Mr. Chesterman and Dr. Sheehan? I would like to see a study of the effect of 1/4 grain morphine given 6-hourly for 48 hours on the passage of a bismuth meal in 20 normal subjects. In the absence of the information which this study would supply, my personal conclusion is that Mr. Chesterman and Dr. Sheehan have demonstrated only that their proposed prophylaxis is not dangerous: it does not conduce to ileus in patients on whom a Caesarean section has been performed. The actual fall in the percentage of cases of ileus in the morphine period is of little significance in view of the fact that the control cases were not "alternate cases," but were cases in earlier years when many points in the handling of the patient must have been different.

The serious side of this paper is that some may conclude that morphine is a prophylactic against ileus after operations on the intestine itself. If we take into consideration all that is known of the action of morphine on the intestine this conclusion is not permissible; morphine is a drug likely to increase the incidence of ileus after such operations. What is fortunate is that there is a well-known drug which is there for everyone to use having none of the dangers of morphine. That drug is physostigmine. Its action is very simple. The movements of the alimentary canal are maintained by the steady synthesis of acetylcholine. This is formed in the gut wall, it exerts its action, and it is then rapidly broken down. Physostigmine delays the rate of breakdown of acetylcholine and so increases intestinal movements in the most natural way.—I am, etc.,

Oxford. J. H. BURN.

Penicillin and Synthetic Rubber

SIR,—Letters have recently appeared relating to the inactivation of penicillin by synthetic rubber tubing. Some time ago the Medical Research Council, jointly with the Ministry of Supply, called a conference to consider the possible uses of synthetic rubber for medical purposes. The members of the conference hope to be able to designate a type of rubber which may be relied upon not to destroy penicillin. It would be helpful if any others who have experienced similar difficulties with inactivation of penicillin would inform me, indicating at the same time the source and history of the tubing used if these can possibly be ascertained.—I am, etc.,

P. G. H. GELL,
Secretary, M.R.C. and Ministry of Supply
Synthetic Rubber Conference.

Ludwig's Angina

SIR,—In view of recent correspondence in your columns by Mr. Hamilton Bailey and Mr. J. H. West *et al.* on the subject of anaesthesia for operation on cases of Ludwig's angina, I feel it is important that case notes on this subject should be given publicity, because of the possibility of sudden regrettable accidents which may occur unless the anaesthetist concerned is reminded of the dangers present in this type of case.

Supporting Mr. Hamilton Bailey's remarks (Sept. 29, p. 440), I would like to add my personal experience of three such cases which occurred during the later weeks of a nine-months period during which I was acting as temporary resident anaesthetist, in addition to my other duties, at a South London hospital recently.

Case 1.—This was in a child of 6 years with Ludwig's angina of undetermined origin. Anaesthesia was induced with gas-and-oxygen, and as soon as a trace of ether was introduced spasm of the glottis developed. Intubation under direct vision was immediately attempted, but was unsuccessful owing to severe glottic spasm; only the fact that an emergency tracheotomy set was readily available and promptly used by an experienced surgeon prevented this child from dying. As it was, several ounces of pus under tension was evacuated after further anaesthesia per the tracheotomy tube. Convalescence was rapid and uneventful. The tracheotomy tube was removed after 48 hours.

Case 2.—This was of post-operative suppurative parotitis in the edentulous woman of 54 years of age, which was at first treated conservatively. As resolution was obviously not taking place it was suggested that I should give a "shot of pentothal" while an incision was made. In view of my experience in Case 1 I decided that a careful induction with gas, oxygen, and trilene would be wiser, a tracheotomy set being handy and the larynx cocainized. Induction was smooth, and on laryngoscopy oedema of the corresponding arytenoid was seen to be present. A tracheotomy tube was passed and operation completed. Several pockets of pus were drained. Local analgesia would have been difficult and imperfect in this case.

Case 3.—This was a case of Ludwig's angina in a man of 37 following evacuation of an infected dental cyst. Post-operative penicillin therapy had resulted in the temperature falling rapidly from 103° F. to normal in three days, but at this time dysphagia was complained of. I recommended local analgesia, and under this a large quantity of sub-mylohoid pus was evacuated per a midline incision. Recovery was uneventful.

I publish these case records largely for the benefit of the less experienced anaesthetist, in the hope that they may avert a tragedy, as my first case nearly was, and in passing to stress the obvious fact, not always remembered, that penicillin, and indeed chemotherapy, will not cause resolution of an established abscess, even though the primary focus may have been promptly dealt with; also to point out (Case 2) that suppurative parotitis may, and did in the case quoted, give rise to dangerous oedema in the region of the glottis. Fortunately dysphagia usually precedes dyspnoea in this type of case. The time interval between unrelieved glottic spasm and cardiac failure in the elderly subject and in the very young, especially when toxaemia is present, allows only a very short period for emergency intubation or, failing this, tracheotomy.—I am, etc.,

Royal National Throat, Nose and Ear Hospital,
London.

Blind Intubation

SIR,—While seconding Dr. John Insley's remarks on blind intubation by way of the nose (Oct. 13, p. 512) I would also like to make a plea for blind peroral intubation, the simplicity, efficiency, and economy of which I can vouch for as a result of long experience.

When the surgical advance of rhino-laryngology demanded intratracheal intubation anaesthesia I used, *faute de mieux*, Kuhn's peroral intubation apparatus. This consists of a flexible metal tube the distal end of which is suitably fenestrated, while the proximal or outer end has a locking device for attaching it to a tube leading to the source of anaesthesia. It is introduced by means of a curved metal obturator attached to a handle. This obturator (which could be readily improvised) has a total length of 14½ in., of which 4 in. are handle. The rectangular curve starts about 7 in. from the distal end of the handle. Finding the metal tubes were clumsy and at times traumatic I substituted rubber tubes, and have since used this method with complete satisfaction. The tracheal end of the tube (the internal diameter of which varies, according to age and sex, from 5 to 10 mm.) is cut obliquely and dipped in sterile liquid paraffin, as also is the curved end of the obturator. The tube when mounted should extend at least one inch beyond the lower end of the latter. After insertion and withdrawal of the obturator the outer end of the rubber tube is connected to the tube from the gas apparatus (or, eventually, to a tube and funnel) by means of a small, curved or L-shaped metal connexion. Before introduction the larynx is sprayed with 10% cocaine solution, after which a pledget of gauze soaked in the solution is applied in the laryngeal vestibule by means of Mackenzie's laryngeal forceps and held until the resultant cough is followed by an inspiration. This can be more pleasantly achieved after general anaesthesia has been induced sufficiently to allow of wide separation of the jaws.

The main difficulties in introduction are obstruction by the epiglottis and the readiness with which the free end of the tube tends to find and enter the oesophageal ostium. To overcome these the index finger of the left hand is introduced to the hypopharynx from the angle of the widely gagged mouth. The *tactus eruditus* of this finger must be such as to allow of quick and accurate location of the epiglottis and of the apices of the arytenoid cartilages, immediately over which latter it retains its position, plantar surface forwards. Upon introduction of the obturator and tube the free end of the latter is made to occupy the potential space between the finger and the dorsal surface of the epiglottis, its oblique tip being directed into the rima glottidis by the finger, which, incidentally, is preventing the tube from entering the oesophagus. Some difficulty may be experienced in a deep larynx or from an unduly large or flaccid epiglottis, but a little patience and experience can overcome this. No force is employed. The actual passage of the rima glottidis is made during an inspiration, and its accomplishment is denoted by the sound of air going through the tube (which should be listened for) and by a short cough.

This method, while it takes time in the telling, can be carried out in a matter of seconds, and I feel that the experienced anaesthetist should be able to do it.—I am, etc.,

Cork.
J. B. HORGAN.

Anaesthetic Risks

SIR,—It is fortunate that Dr. E. Falkner Hill (Oct. 13, p. 511) has answered Dr. John Elam's unbalanced judgment on spinal anaesthesia. Notwithstanding certain disadvantages attached to spinal anaesthesia, there is a large body of experienced surgeons who will agree that it plays a very important part in surgery, and most certainly in the upper abdomen. Figures, when sanely considered, are a help.

The following figures show the death rate in this hospital after partial gastrectomy for duodenal ulcers, excluding all cases of severe haematemesis or melaena at the time of operation:

Period	No. of Cases	Anaesthesia	Deaths	Mortality
1931–5	99	General	9	9% approx.
1936–9	125	Spinal	4	3·2% ,,

It was in 1936 that the routine for these cases became a spinal anaesthetic.

I should not like to give the impression that this improvement in mortality is solely due to a change in the method of anaesthesia, but it is quite likely that it was a very important factor in the improvement. Just to make certain that 1936–9 figures were not accidental, the figures for gastrectomies for duodenal and gastric ulcers (again excluding active bleeding ulcers) for 1942–5 (June) are given:

Period	No. of Cases	Anaesthesia	Deaths	Mortality
1942–5 (June)	205	Spinal	3	1·5% approx.

Spinal was used as the principal anaesthetic. Two surgeons supplemented this with pentothal and gas-and-oxygen with a little ether or trilene to maintain sleep. Another surgeon used spinal anaesthesia only, with local infiltration with novocain along the upper end of the lesser curve during 1944–5. This series included two cases with open pulmonary tuberculosis.

The surgeons at this hospital, present and past, do not suffer from any delusions about this mortality rate. They consider that 1.5% mortality is fortuitous, even though it is in a series of over 200 cases. They feel that a mortality rate of 3 to 4% is a more accurate figure over a larger series of cases. There is one point about which neither surgeons nor anaesthetists have any doubt whatever. It is that in their hands it has made partial gastrectomy safer for the patient and less anxious for the surgeon.

In my opinion Dr. Elam would be doing a great disservice to surgery if he succeeded in dissuading surgeons and anaesthetists from using spinal anaesthesia. It goes without saying that the greatest care is needed in its administration.—I am, etc.,

Miller General Hospital, S.E.10.
F. H. MASINA.

Longevity

SIR,—Most statisticians would agree with the conclusions reached by Dr. A. Forster in his interesting letter (Oct. 20, p. 545). We have not at present enough accurate data of survival to reach statistical results much better than guesses. There is a small point, of no practical importance but biologically interesting—namely, Is it *impossible* or only *very improbable* that a human being should live to the age of Methuselah ?

Some years ago Dr. J. O. Irwin and I made a study of the bio-statistics of senility (*Human Biology*, 1939, **11**, 1–23). The most exact data we had related to 240 female and 50 male annuitants who had attained the age of 90 in the years 1920–2 and were under observation until death. None of the males survived to 100; 4 females lived to 100, and one to 102. Of course, graduating such scanty numbers is not much more than an amusement, but we found that they were not badly smoothed by a formula which involved the ultimate constancy of q_x—i.e., the probability of dying between the ages of x and $x+1$, for a value of q_x much below unity—0.439 for women, 0.544 for men. Now *if* this were verified by an experience of not 240 but hundreds of thousands of lives observed from the age of 90 to death, it would imply that the length of days of Methuselah is not an impossibility but merely a very improbable event. If the limiting value were 0.5, then the chance of a centenarian beating old Parr's alleged record would be 0.5 raised to the 52nd power—a rather small fraction, but still finite. It would be interesting if someone with leisure would collect more data. Modern annuitant experience no doubt does not run to hundreds of thousands of lives beyond 90, but surely to some thousands.—I am, etc.,

Loughton. MAJOR GREENWOOD.

Psychiatry in the Services

SIR,—I read Wing Cmdr. K. G. Bergin's letter (Oct. 13, p. 508) with great interest. As a neuropsychiatrist working in an E.M.S. hospital for the past five years I have had ample opportunity of assessing the reactions of Service personnel to psychiatric interference. It is a well-known fact that attempting to cure neurosis is an almost hopeless task when the patient is obtaining some advantage in his present environment by being ill.

However, I would not agree that such individuals "have, by conscious or unconscious deception, achieved their object." In my experience actual deception is rare, and in the vast majority of cases the symptoms are truly neurotic—i.e., expressions of disordered emotion over which the sufferer has no control unless given further insight. Had the psychiatric reports referred to gone a little deeper they might, in nearly all instances, have given evidence of unhealthy emotional attitudes in childhood, usually engendered by unsatisfactory home influences, and leading to the acquisition of fixed modes of reaction which the individuals are doomed to carry with them for the rest of their lives. It would appear that childhood experiences act as a prototype for future orientation to society, and just as trained animals bring forth their conditioned responses on the slightest provocation and without thought, so may it be truly said that the child is father to the man.

Since neurosis is thus usually a lifelong complaint with recent exacerbations due to excessive stress, it is not surprising that it takes a long time to eradicate, and anybody who hopes to be able to do this under the limitations of time imposed by the necessities of Service life is not a psychiatrist but a fool.

However, there is always the other aspect—social adjustment, which in the case of the Services means the ability or otherwise to make a useful contribution to the common effort. Most neurotics are capable of so contributing provided the motivation is strong enough, and as the mere fact that they are not doing so is an indication that the usual motive of duty to country is not effective with them, some other—i.e., escaping punishment —might well prove an effective substitute. If this line of approach were to prove a success under wartime Service conditions one cannot help wondering how far it would act in peacetime.

During recent years it has been very noticeable how many hospital out-patients have imposing symptoms which, on careful investigation, prove to be without physical foundation. During an inquiry into possible psychological factors one usually gets the request for "a note for the Labour Exchange" recommending transfer from the present job, to which they have been directed, to another, usually more pleasant, of their own choosing; compliance with such a request nearly always results in a dramatic relief of symptoms. But it is still a fact that nearly all such cases are true neurotics and that deliberate malingering is rare. Is one to take the attitude that such people are not pulling their weight and are therefore enemies of the State, to be dealt with by harsh methods, such as the suggested imprisonment, until they decide to stop making capital out of their weakness ? If so, the results might be amazingly good from the point of view of checking invalidism, but does this not imply an altered medical outlook—i.e., the patient is no longer entitled to health for its own sake and as a means of helping him to enjoy life more, but only so far as it fits him for contributing to the total effort of the State ?

There is an unpleasant element of totalitarianism about such methods, which are also not without their dangers. For example, I know of at least two soldiers whose complaints had been dealt with after the manner suggested by Wing Cmdr. Bergin who confided to me that they had obtained a loaded rifle and lain in wait for their oppressors, fortunately changing their minds at the last moment. Mass outbursts of delinquency among the general public are not pleasant to contemplate. Is it not possible that the incidence of neurotic breakdown in the Services is largely determined by the restrictions on personal liberty which have necessarily to be imposed ?—I am, etc.,

Bromsgrove. J. L. CLEGG.

SIR,—I was very interested to read Wing Cmdr. K. G. Bergin's letter, as it raises problems which some of us have been trying to solve for some years past. Let me assure him that the average Service neuropsychiatrist is as cynical as himself, and only too well aware of the fact that his patient may make a rapid recovery just as soon as he is sure of his "ticket." But whether it be pandering or no, it is surely good, sound common sense to place "bad psychiatric bets" in low medical categories. Constitutional inferiors and hysterics have not been wanted on active service during the war as they have an unpleasant tendency to break down at awkward moments and exert an undesirable effect on the morale of their comrades. That they are encouraged thereby to persist in their symptoms, with invaliding as their eventual goal, is unfortunate, but probably inevitable. It is no new thing to discover that punishment will frequently succeed where other forms of treatment have failed; but the punishment must represent something worse to the patient than the ordeal which he is hoping to avoid. For example, it is not going to cure a hysteric to send him to detention for twelve months if thereby he misses a series of Russian convoys.

In 1942 the Navy opened a special camp to which those who were suspected by psychiatrists of making the most of their symptoms could be drafted. They were under executive command and subject to ordinary Naval discipline; their symptoms were ignored so far as possible, and no limit was set to their retention in the camp. By such means it was found possible to salve many who would otherwise have required invaliding, but careful placing in various forms of restricted service was necessary in the majority of cases to achieve this result. But the chief value of this unit lay in the fact that the depot psychiatrist could assure the "non-trier" that there was no "ticket" for him, but a draft to a nasty place if he did not begin to help himself. Even so, a large number of hysterical and inferior personalities proved resistant and required invaliding.—I am, etc.,

R. R. PREWER,
Surg. Lieut.-Cmdr., R.N.V.R.

SIR,—The letter of Wing Cmdr. Bergin contains just that kernel of truth that so often makes so much mischief in generalities. There is none amongst us who has spent the years of war in the Services who has not seen just the case he describes: the man bordering on the anxiety state, a constant burden to his medical officer with his manifold complaints, until finally he is invalided on psychiatric grounds, often to recover with amazing rapidity as he returns to his more normal environment. Must the psychiatrist and the system be condemned if this man is happily healed and the Service rid of one who can never be other than a liability?

Wing Cmdr. Bergin, writing no doubt as a medical administrator, treads on dangerous ground if he further inculcates in others the unjust attitude of mind that the Service doctor should think of those who complain of such symptoms as he describes first as scheming "racketeers" and only secondly as the sick in search of relief. There is no essential difference between the symptoms and the ills of those in the Services and those we treated in days of peace. A few, a very few of each, in both the Services and civilian life, make much of their malady with an end in view; the remainder, the huge majority, have aches and pains for which an organic cause may or may not be found, perhaps depending not a little on the diagnostic acumen and enthusiasm of their doctor, but for which they earnestly and rightly seek help to be rid of. What matters it whether the surgeon or the psychiatrist succeeds? Let us as doctors in the Service remain clinicians primarily, seek for our cures first through the science of medicine, retain the spirit of detached sympathy, and leave the cynicism to others.—I am, etc.,

G. A. JAMIESON,
Wing Cmdr., R.A.F.V.R.
Inverness.

SIR,—Wing Cmdr. K. G. Bergin (Oct. 13, p. 508) should be very careful. He is on dangerous ground. He talks great wisdom when he speaks of "a system which lays too much stress on psychological illnesss and not enough on a man's responsibility to his fellows," because lack of this responsibility, or, more positively, the weakness of selfishness, is probably the most common fault of us all, beginning in childhood. But of all systems to-day modern psychiatry is not the offender to be taken to task. An experienced medical psychologist is very much concerned with responsibility to one's neighbour, for this is the very essence of his definition of sanity.

If the individual Army psychologist happens to invalid out of the Army some cases which Wing Cmdr. Bergin finds curable by the no less worthy psychological method of punishment, then indeed we may claim the converse to be true—that a future suicide might be punished instead of being discharged to "carry on a greyhound business" or "cycle merrily home five miles to work in his garden." It may be some years before he joins the ranks of those poor wretches who blow their brains out in the Army or reach the overcrowded mental hospitals. Indeed, Wing Cmdr. Bergin might never hear of the incident, but if the decision were his then his responsibility to that individual, his neighbour, would remain.

Furthermore Army psychiatry is a child of 5 years of age; its members are many of them inexperienced. If its inexperience leads to the lame leaping for joy, the blind seeing, and dyspeptics eating large indigestible meals, then it has a powerful future. But I feel that even psychiatrists cannot produce this Christ-like scene of joy. The majority of the men and women discharged from the Services for neurosis are now being treated under the after-care scheme of the Board of Control.—I am, etc.,

Surrey. JOHN A. MCCLUSKIE.

SIR,—I am sure that Wing Cmdr. Bergin's eminently sensible and vigorous letter crystallizes the views of many serving medical officers who have had to treat "those unwilling to bear the heat and burden of the day." As an Army dermatologist I have wasted much time attempting to treat such patients; those whose somatic manifestation of a disturbed psyche takes the form of a rubbed and excoriated dermatosis are known to all dermatologists. There appears to be no answer to cases of this type. Continuous narcosis, occlusive dressings, and appeals to their non-existent better natures may lead to a temporary remission, but there is an invariable relapse once they return to their uncongenial environment. A number of these patients spend a period under detention for absenteeism, but many escape from this with their lesion conveniently secondarily infected (they avoid reporting sick until it is in this state), and spend the remainder of their sentence in the comfort and security of a military hospital skin department, where they enjoy the same amenities as those invalided from operational theatres over-seas.

A few months of military dermatology make one realize that these patients are a liability to the Army Medical Service, and they are eventually written up for a medical board which will invalid them out. While awaiting their board one observes, in the less astute, the transformation to which Wing Cmdr. Bergin draws attention. The hang-dog look disappears, and the traumatized skin heals with amazing rapidity. Should the medical board decide, however, that the patient's disability does not warrant discharge there is an equally rapid relapse. In brief, these patients literally scratch their way out of the Service. Unlike those of their brethren with vague headaches and dyspepsia of nervous origin they have something "to show," which enables them to preserve their ego; at the same time they possess a most effective lever for escape.—I am, etc.,

PATRICK HALL-SMITH,
Capt., R.A.M.C.
Hove.

SIR,—I was touched by Wing Cmdr. Bergin's cry from the heart, and would beg the hospitality of your columns in order to offer him a little solace in the difficult formative period through which he is now passing.

It should comfort him a good deal, in the first place, to make him aware of some of his more glaring factual inaccuracies. In all Services during the war the rate of return to full duty of psychiatric cases has been about 80%, and far from this being "most disappointing" it has sustained mightily those whose work has lain in this field. In the second place, he himself gives, with admirable clarity, the chief reasons for disappointing results. If Wing Cmdr. Bergin always ensures that every psychiatric patient has a "clean bill of health" from every other specialist to whom he has access, and then refers his case to a psychiatrist in a spirit of "diagnostic destitution," then he must not be surprised if results are not always what they ought to be. Promptness of diagnosis, early treatment, and disposal are the keystones of management in these cases, as has been emphasized in the war literature over and over again. However, I think it would be a great mistake to assume that this practice, mentioned by Wing Cmdr. Bergin, is widespread or even common. A very large majority of medical officers with Service experience can diagnose these cases quickly and competently, and, where an ill is a minor one, treat them very satisfactorily. All psychiatrists would agree that it is no more desirable to refer every psychiatric case to a psychiatrist than it is to refer every sprained ankle to a surgeon or every case of wax in the ear to an E.N.T. specialist.

I could not understand why Wing Cmdr. Bergin should be troubled by an autogenous cynicism because his patients showed a decent and restrained jubilation at the prospect of being invalided. I have not observed deep depression as a common phenomenon in the pre-invaliding phase in any type of patient, whether psychiatric or not. It is worth recording, indeed, that great unhappiness at the prospect of invaliding is a very common feature of schizophrenia.

I would whole-heartedly agree with his observation that imprisonment is beneficial in many psychiatric reactions. There is little that is novel in this observation, for it was observed many, many years ago that the regular routine life, good food, and open-air conditions of a well-ordered prison might produce beneficial results in the psychoneurotic. There are, however, certain difficulties about adopting this as a consistent mode of therapy. In the first place, psychotic reactions have not been observed to benefit, nor do the more severe types of depression appear to improve, under these conditions. There is also the trifling matter of the ethical justification of such procedure. I do not doubt, of course, anything Wing Cmdr. Bergin says, but I can only wonder at the truly remarkable spirit of co-operation shown by his executive colleagues, who will collaborate with him in this novel mode of treatment.

Finally I would like to commend the thesis of incapacity, as opposed to unwillingness, as an object of Wing Cmdr. Bergin's most serious study, for there is a very definite school which accepts the existence of mental illness as opposed to the thesis of calculated villainy. I should estimate this school as amounting to some 99% of the medical profession, and it must, therefore, if only by virtue of numbers, command some respect.—I am, etc.,

GERALD GARMANY,
Surg. Lieut.-Cmdr.
R.N. Auxiliary Hospital, Barrow Gurney.

Fenestration for Otosclerosis

SIR,—As one who has taken an active interest in fenestration for otosclerosis continuously since 1932 I read your leading article on this subject (Sept. 29, p. 430) and also the three letters by Messrs. N. Asherson, E. Carew-Shaw, and E. R. Garnett Passe (Oct. 13, p. 509). While I entirely agree with the admirable balanced remarks of the first and last named writers, I cannot agree in any respect with those of Mr. Carew-Shaw. There is no getting away from the fact that the region of the labyrinth is one where unskilled, half-trained, or injudicious surgery is fraught with the greatest danger. "Fools rush in where angels fear to tread," and to suggest that the operation need not "remain in the hands of a few with special aptitude" to my mind is asking for trouble, and it is certain sooner or later to bring this procedure with its definite field of usefulness into discredit. Rather let it only be performed amid ideal surroundings, and let it remain in the hands of those competent aurists who *have* studied the anatomy and the technique and, by repeated experimentation on the cadaver, have acquired that intimacy with the fine points of the operative steps which alone can ensure freedom from risk and a reasonable chance of satisfactory results.

The operation, whatever may be said to the contrary by the few, is definitely an intricate one, and therefore must never be embarked on by anyone with a passion for "operating against the clock."—I am, etc.,

Salisbury. C. A. HUTCHINSON.

Acute Inversion of the Uterus

SIR,—I was very interested to read Mr. J. V. O'Sullivan's article on the treatment of acute inversion of the uterus (Sept. 1, p. 282), and would like to add yet another instance of his method having been used with success.

A primipara, aged 23, was admitted to St. Helier County Hospital at 7.20 p.m. on Sept 29. She had had a normal delivery of a 7½-lb. child in a local nursing home at 6.10 p.m. The first stage lasted 10 hours, and the second stage 2 hours and 10 minutes. Severe post-partum haemorrhage (2–3 pints) had necessitated an attempt at expression of the placenta, and this resulted in complete inversion of the uterus at 6.35 p.m. On admission she appeared to be moribund, and the accompanying midwife had felt sure she would die in the ambulance. Her colour was grey and the pulse imperceptible. Before attempting any other examinations, blood transfusion was started and she was given 2 pints under pressure within half an hour of admission. This resulted in very slight improvement, and it was just possible to feel radial pulsation, though the rate was uncountable and the blood pressure could not be recorded. At 8.30 p.m., after further transfusion and methedrine, she was exposed sufficiently to make a gentle examination of the uterus. The placenta was found to be almost completely adherent to the fundus, which extended half-way down her thighs. There was only slight bleeding. The patient's condition deteriorated after this minimal interference, and our idea of peeling off the placenta and replacing the uterus in the vagina was therefore abandoned. Transfusion was continued until 9.30 p.m., when she had had nearly 8 pints of Rh-negative blood. She was steadily getting worse, had lost a further pint of blood, and appeared to be at the point of death. It was decided that the only possible treatment was to remove the placenta and replace the uterus. She was anaesthetized with cyclopropane, the placenta gently peeled off with some difficulty, and the uterus eased back into the vagina. A "dettol" douche was then used to balloon the vagina, and the uterus immediately returned to the abdomen. Ergometrine was given intravenously and intramuscularly.

There was a dramatic improvement. Half an hour later the blood pressure was 140/70 and her pulse could be easily counted at the wrist, though its rate was 156 per minute. The transfusion was stopped. Improvement was maintained till 11.30 p.m., when she suddenly became severely shocked again, with an uncountable pulse and a systolic blood pressure of only 60 mm. The uterus was firmly contracted and there was not any vaginal bleeding. Methedrine was given and transfusion started in a saphenous vein, but the peripheral circulation was so poor that it was difficult to keep it running fast. During the next three hours there was gradual improvement. The blood pressure rose to 90/40 mm., and her pulse rate fell to 150–160 per minute. By that time she had had 10 pints of blood in all, and a slow saline drip was continued for a few more hours to ensure the patency of a vein should she get worse. At 7.30 a.m. her pressure was 104/70 mm. and the pulse rate 140 per minute. Since then she has not given us any cause for anxiety, though her haemoglobin two days later was only 54%. Serology has not shown any evidence of haemolysis. Prophylactic sulphadiazine and *B. welchii* serum were given, and her temperature did not rise above 100.4° F. She was apyrexial six days after delivery, when she was given a transfusion of 400 c.cm. packed red cells. She was discharged on the sixteenth day with a haemoglobin of 72%.

I feel certain that this woman would have died if we had not known of this simple method of correcting the inversion. It was interesting that such strenuous efforts to combat the shock were quite ineffective until replacement was carried out, and it would seem advisable in similar cases to interfere at once if resuscitation by the usual methods failed, no matter how desperate the patient's condition.

I am most grateful to Mr. O'Sullivan, who was good enough to come and give us invaluable help in the management of the case.—I am, etc.,

Carshalton, Surrey. DOREEN DALEY.

Volvulus of Small Intestine

SIR,—The report of a case of volvulus of the small intestine by Major R. Salisbury Woods prompts me to recount a case I had in September, 1944.

The patient was a married woman aged 33, multip. 5 months; before marriage she was a sister at the local hospital. On Sept. 28, 1944, about 4 a.m., I was called to see her on account of a sudden acute abdominal pain and vomiting. No previous history of abdominal pain or discomfort. No previous operations. Temperature and pulse normal. Pain referred to lower abdomen. No distension and no tenderness. Bowels open the evening before. An enema given later in the morning produced a good result, and was followed by complete relief. Seen again the evening of Sept. 28; no pain and quite comfortable.

While operating on the afternoon of Sept. 29 I received a telephone message from the husband to say that his wife had more acute abdominal pain and had been sick several times. I had her admitted into hospital at once, and when I saw her about half an hour later she was in great pain; the abdomen was distended and there was an irregular tender mass to be felt in the lower abdomen to the left of the midline. I opened her abdomen one hour later—midline subumbilical incision—and found a complete volvulus of the last foot of small intestine, which was due to the bowel becoming attached to a large "solitary" caseating gland in the mesentery of the small intestine. The gut was black and showed no signs of recovery on unwinding the volvulus. About a foot of small intestine was resected and an end-to-end anastomosis performed. The offending gland was removed. She was a grand patient and made an uneventful recovery.

On thinking over the case, although I was somewhat dismayed to find a gangrenous bowel at operation I did not feel justified in opening her abdomen sooner than I did. As in Major Salisbury Woods's case, it is obvious now that the early signs and symptoms were (to quote his apt description) "due to a subacute volvulus in which the affected loop was swinging like a ship at anchor, partially folding over and then swinging free again until it 'stayed put' some 36 hours later." Despite diet and various medicines the bowels are a little troublesome: 2 to 3 times a day, and there is nearly always a fairly urgent call; otherwise all well.—I am, etc.,

D. J. P. O'MEARA,
Bury St. Edmunds. Hon Surgeon, West Suffolk Hospital.

SIR,—I was very interested in the note by Major R. Salisbury Woods on volvulus of the small intestine (Oct. 13, p. 496). I agree that under the conditions of European practice it is a rarity, but this is not so everywhere. Between 1919 and 1932 while working in the western United Provinces of India I had occasion to operate on about 60 cases of intestinal obstruction (apart from strangulated hernia), and of these no fewer than 12 were cases of volvulus of the small intestine. Why the condition should be common there is not clear, but the following facts are suggestive.

"Intestinal colic" with constipation is very common in India. The traditional treatment is castor oil and opium, which soon relieves the milder cases, however unorthodox and alarming to

Western ideas. But the more severe cases approach the character of intestinal obstruction, with marked distension, shock, and even vomiting of intestinal contents, though sudden relief may come after repeated large slow enemata or even without treatment.

Indian patients refuse operation as often as not, and of those whose condition justified a diagnosis of obstruction by all ordinary standards a surprising number (about one-fifth of the total) recovered after one, two, or even three large slow enemata. One patient was so ill that he died a few minutes after a third enema had produced a copious watery motion. At necropsy it was evident that a volvulus had existed and become unwound. The affected loop was increasingly congested as one traced it downwards, with many ecchymoses, especially on the anti-mesenteric border. The congestion ceased abruptly at the lower end, and on the root of the mesentery was a deep groove where the bowel had crossed it. This is exactly the picture found at operation after relieving the severer cases of volvulus of the small intestine. In another obstruction case I found what I believed to be a later stage of the same picture. A year after a severe "colic" attack I found a large loop bound down at both ends to a scarred and thickened mesentery. Here the damage must have been greater, for at the scarred upper end was a stricture which had brought the patient to the operating table.

It is remarkable that both "colic" cases and those of volvulus nearly always gave a history of a large meal of coarse, indigestible food—badly ground millet, half-cooked grain, or certain green leaves (gunyan), all of which have the reputation of giving colic. From a search of such literature as was then available to me I gathered that volvulus of the ileum was not uncommon in Southern Russia, where the poorer classes consume large quantities of millet and other coarse grains. From these facts I believe that volvulus of the small intestine is not unusual in races whose food leaves a large indigestible residue (Indians excrete twice as much faeces as Europeans), and that spontaneous resolution is quite common.

I am in complete agreement with Major Salisbury Woods's picture of the loop folding over and then swinging free again, and I agree that in early cases when congestion is slight the appearances are so puzzling that the condition is easily overlooked. Eventually I learnt to recognize the volvulus by sweeping a finger round among the intestines in the right lower quadrant of the abdomen when it encountered a band of resistance. It was, I suppose, the pedicle of the volvulus; at any rate there was something going back to the lower part of the root of the mesentery which did not slip away before the finger as it should.

In these Indian cases the volvulus involves several, even many, feet of the ileum, and it is quite difficult to be sure when the reduction is complete without more manipulation than one likes. The affected coils contain little gas and may be very heavy with liquid contents and undigested food, which may account for the production of the volvulus.—I am, etc.,

R. C. McWATTERS,
Military Hospital, Penshurst. Lieut.-Col., I.M.S. (ret.).

Operation for Varicose Veins

SIR,—Mr. Harold Dodd (Oct. 13, p. 510) has done a great service in calling attention to the importance and difficulties of this subject. His statement in which he advocates that a "pool" of information is necessary brings out the fact that there is no 100% cure for varicose veins, and that, furthermore, there are many and varied opinions and techniques being practised by those interested in this fascinating subject. Most of us will agree that the operation is one which calls for the greatest care, and should be treated as a major surgical procedure. Economic conditions and the shortage of beds necessitate in many instances the use of out-patient procedure. However, even though this may be a necessity, such operations should be performed in a major theatre with all facilities for absolute sterility and for expert assistance. My attention has been called recently to certain tragedies which might have been avoided had these points been better appreciated. To mention a few: sepsis, sloughing from sclerosant injections, emboli, tearing of the femoral vein, and even ligature of the femoral artery, have occurred in the hands of qualified practitioners. The fetish of a minute incision performed in a poorly equipped out-patient theatre should be discarded.

Again, the use and abuse of sclerosants at *the time of the operation* is a subject which calls for further investigation. There are two schools of thought in this matter. Should both legs be dealt with at the same operation, or should the operation come into line, say, with that of double hernia, in which I believe the practice of dealing with one side at a time to be the usual procedure?

There are countless other "differences of opinion," and there seems to be but little correlation of the late results following the various and varied techniques. Mr. Dodd's letter will have been a great service if it serves to call together those of us who are struggling with this problem of the vagaries of the varix. —I am, etc.,

London, W.1. R. R. FOOTE.

Nerve Injuries in Children

SIR,—I should like to thank Mr. St. Clair Strange and Mr. Zachary (Oct. 20, p. 545) for their letters correcting the obvious mathematical error in my article of Oct. 6. The figures should have read 15 mm. a week and not 15 mm. a day. This is in line with Mr. Zachary's figure of 2.1 mm. a day.

Although 2.1 mm. a day does not appear to be a great increase upon the oft-quoted figure of 1.0 to 1.5 mm. a day for the rate of recovery in an adult, it is in my opinion much greater than the figures suggest.

The rate of recovery of nerve injuries in adults is very rarely as rapid as 1.0 mm. a day. In fact, the rate of recovery in adults in our own cases and those of other surgeons, which we are treating, is disappointingly slow.

The case referred to in my article of Oct. 6 was seen in May, 1944, in the out-patient department of the Royal National Orthopaedic Hospital, Great Portland Street, and was operated upon two weeks later. Both before operation and twelve weeks after operation she was also examined by my colleague, Mr. Donald Norris. The patient, Miss P., is now employed in the telephone exchange of the Royal National Orthopaedic Hospital, Stanmore, and is most co-operative in demonstrating her result to anyone who may be interested.—I am, etc.,

Royal National Orthopaedic Hospital. E. HAMBLY.

Caffeine and Peptic Ulcer

SIR,—Your annotator ends his article (Oct. 13, p. 504) with these words: ". . . at least an adequate justification for eliminating caffeine-containing beverages from the diet of ulcer patients." Why not put it in plain English? Ulcer patients are not to be allowed tea or coffee. Now the cup of tea is an institution without which no charlady, Service man or woman, private or colonel would complete a day's work. Tea was one of the few luxuries that Lord Woolton maintained during the blackest period of the Battle of the Atlantic. It fetches an enormous price in the "black market" on the Continent.

What is the evidence for its denial to the ulcer patient? An American youth who perforated after drinking 150 bottles of coca-cola; a resistant duodenal ulcer in a patient who was a coca-cola addict; experiments on cats which show they develop engorgement of the gastric mucosa after the injection of 250 mg. of caffeine sodium benzoate (the equivalent weight for weight of an average man drinking 50 cups of tea). It is difficult enough to persuade an ulcer patient to stick to a regime, but to deny him tea and coffee on these grounds will undermine any faith he may have in his doctor.—I am, etc.,

R.A.F. Station, Keevil, Wilts. J. S. ASTBURY.

Epidemic Diarrhoea and Vomiting

SIR,—We have read the very interesting paper on epidemic diarrhoea and vomiting, etc., by Drs. George Brown, G. J. Crawford, and Lois Stent (Oct. 20, p. 524), and think that our experiences during an outbreak in July, 1945, in this hospital might be of interest to your readers.

This hospital has a population of about 2,000 patients and resident staff, but the outbreak was practically restricted to female staff and patients. Altogether about 130 out of a female population of 1,300 became ill. This is all the more remarkable as one of the female wards with a morbidity of about 25% lies within the "male side" of the hospital. This is a female infirmary ward, and the patients are not much in contact with other patients. We could not find out how the disease spread to this ward. Both staff and patients were involved, but the first nurse fell ill four days after the first patient, so that it does not seem likely that the nursing staff were the carriers; we thought one nurse might have been a carrier but were unable to find proof. The very few male patients affected fell ill only towards the end of the epidemic, so it is unlikely that it started on the male side. Another remarkable feature was that in spite of precautions the disease spread rapidly within the female wards affected, with a morbidity of between 10% and 50%, but it did not spread at all in the male wards. In one six-ward block all wards were affected, and in a second only four wards were affected. The epidemic started slowly on July 1 and petered out towards the end of the month.

Bacteriologically, we did not find any non-lactose-fermenters at first, but later on, when strict orders had been given to send the very first diarrhoeic stool passed—and this was not always possible—a number of non-lactose-fermenters, not of the typhoid-dysentery group, appeared. The table below contains the detailed findings in fifty cases as compared with the same number of stools examined as a routine. It shows a considerable percentage increase in the number of organisms regarded by some workers as pathogens but by others as concomitants only.

	Routine Material	Epidemic Material
Negative	45	36
B. faecalis alcaligenes	1	3
B. coli anaerogenes	—	1
B. morgani	—	3
N.L.F. *B. coli*	—	1
B. paracolon types	3	2
Others	1	4
Total	50	50

Under the item "Others" we include five organisms which were non-lactose-fermenters but which gave varying fermentation reactions and which could not be identified serologically.

As the illness was definitely a clinical entity, while the bacteriological findings were not, the results support the views of those authors who think that these organisms grow more freely in diarrhoeic stools but have nothing to do with their causation. Unfortunately the disease occurred during a shortage of medical and laboratory staff caused by the holiday period and other reasons; consequently it was not possible to investigate the haematology, etc., and we could not even make a deductive guess as to the origin (bacterial or virus) of the epidemic.—We are, etc.,

Shenley Hospital, St. Albans.

Young Nurses in Tuberculosis Wards

SIR,—A circular has recently been issued by the Ministry of Health which indicates that the Minister is not prepared to take action to stop the recruitment of very young girls—mere children, indeed—for work in acute tuberculosis wards. Here is a definite instance.

On her 16th birthday M. B. started a nursing career in a borough isolation hospital, being put to a tuberculosis ward. Within a few weeks she was under treatment for erythema nodosum, but soon returned to work, this time on night duty. Within a few months she complained of an aching knee and of feeling "so tired"; she was told this was a quite common experience. Her 17th birthday found her entering a tuberculosis hospital as a patient with established disease of lungs, knee, and kidney. Two and a half years later she was still there, hovering between life and death.

In the nursing papers advertisements were still appearing for girls of 17 or under for this same isolation hospital, which is a unit in the Public *Health* service of this country.—I am, etc.,

Northwood. ESTHER CARLING.

Doctors in Uniform

SIR,—It has occurred to me, in reading the many letters published in your *Journal* from R.A.M.C. officers complaining of their lot, that few of them have approached their Service from a realistic point of view. Their complaints may be summarized into two main groups: (1) lack of professional work, and (2) complaints generally about the administrative and disciplinary aspects of the Services.

Under the first head the fault is, I think, that some medical officers failed to realize that they held commissions in the Army and regarded themselves as doctors only—not accepting the fact that they belonged to the most fortunate profession in wartime in so far that they were allowed to continue with their profession in some degree, in contradistinction, say, to a lawyer or other professional man who might be an infantryman or a gunner. In other words, "there was a war on" and "there were regimental duties to be done." Incidentally they were paid at a higher rate than any other Services, and some of the grumblers even had exalted ranks. In my experience the good and keen regimental medical officer seldom complained of lack of work, and many of them were indeed overworked. War inevitably at times produces for everybody periods of boredom and inanition.

The second complaint is largely explained, too, by the above; but in addition there was an undercurrent of distrust of the regular R.A.M.C. officer, and a reaction that any instructions issued by him must be professionally inadequate and administratively bound up with red tape. Nothing could have been less true. The majority of the Regular officers it was my privilege to serve with were first class professionally, and were certainly better read and informed on non-professional subjects than their civilian counterparts.

Most of the complaints I heard were the result of ignorance of the duties of an R.A.M.C. officer on the part of the complainants. So many admitted that they were only interested in medicine, and resolutely refused even to try to learn or understand Army procedure. Of course I am only speaking of the grumblers. The large majority of the emergency commissioned officers tried to learn the new aspects of their job, and succeeded in learning them, as the wonderful record of the medical services in this war clearly shows.

May I add that I speak as a non-Regular. My experience of the Territorial Army dates only from July, 1939, but I am grateful for having had the honour and opportunity of serving with the R.A.M.C.—I am, etc.,

L. J. HAYDON,
(Late) Lieut.-Col., R.A.M.C.

Rehabilitation of Skin Patients

SIR,—You published a very excellent paper on "Rehabilitation of Patients suffering from Skin Disease" by Major R. Mason Bolam (Oct. 20, p. 539). In it he describes the work done at Ragley Hall British Red Cross and St. John Auxiliary Hospital in Worcestershire. It is one of the hospitals which was included in my area as Inspector for War Organizations during the last six years. I have repeatedly in my reports on this hospital pointed out to the Director of Medical Services, General Ainsworth, the excellent work which I have witnessed here. I should like to say how much I endorse everything that Major Bolam says and how thoroughly I agree with his conclusions at the end of his paper. May I add that the organization and treatment could only have been carried out by a wonderful team of workers. I refer, of course, to the Commandant and the Matron and her staff: they certainly deserve all the praise that can be given.—I am, etc.,

R. G. HOGARTH, F.R.C.S.,
Inspector of Hospitals for Regions 9 and 3.

Nottingham.

Permission for Aliens to Practise

SIR,—I wish heartily to endorse the plea made by Dr. Harold Sanguinetti (Oct. 13, p. 514) for allowing "enemy alien" doctors to continue to practice their profession in this country. I would also add that the permission should include "friendly alien" doctors who may have unhappy memories which they do not wish to awaken by returning to their own countries. I believe it is against our principles of humanity to force those to whom we have given refuge to return against their will, and unfair to use their services for our advantage and dispense with them when our need is less critical. Apart from the justice of the matter, it would appear from the numerous articles which have been written recently that there will be a great shortage of doctors for many years, so the services of any foreign doctors who care to remain can only be of advantage to this country.

While I hesitate to believe that the Government is waiting for an expression of medical opinion, I do think such an expression would be helpful, and appeal to all those who agree to ensure that their views are made known in the right quarter.—I am, etc.,

Leicester. JANET M. DONE.

Obituary

SIR LISLE WEBB, K.B.E., C.B., C.M.G.

Brevet Colonel Sir Arthur Lisle Ambrose Webb, who died on Oct. 7, was born on July 19, 1871. He received his medical education at University College Hospital, London, and took the Conjoint qualification in 1895. At the outbreak of the South African War in 1899 he was a district surgeon under the Basutoland Government, and immediately resigned his appointment and joined the R.A.M.C. He served throughout the war, for which he received the Queen's Medal with five clasps and the King's with two clasps. After the war he took the diplomas in public health and tropical medicine and hygiene. During the war of 1914–18 he served as an Assistant Director-General of Medical Services, and was mentioned in dispatches, awarded the C.M.G., and given the rank of brevet colonel. For his service during that war he was further, in 1919, awarded the C.B.

After the Armistice in 1918, and the consequent mass demobilization, the Ministry of Pensions was faced with the task of assessing the amount of disablement suffered by the many thousand claimants for compensation, and of providing in- and out-patient treatment where necessary. Lisle Webb was appointed Director-General of Medical Services to carry out this task, and in a comparatively short space of time medical boards were in continuous session throughout the country, and hospitals and clinics for the exclusive needs of ex-Service men were established in the large towns. Webb's work in this connexion was rewarded by the well-merited honour of K.B.E. He had been seconded to the Ministry from the R.A.M.C., and later it became a question whether he should return to the Army or not. He was, however, so obviously the man to continue directing the work which he had begun so well that his appointment in the Ministry was confirmed, and he retired from military service and became a civil servant. He continued in this position until the end of 1933, when he retired. Webb's success, while due largely to his own inherent ability, was in no small measure contributed to by the willing and efficient service rendered by his staff to a chief who considered them in every way. A piece of work well done won from him the praise which incited to fresh efforts; work was never allowed to accumulate while an official was on leave; any indication of overwork or ill-health was always met by an instruction to take the necessary rest.

When he retired in 1933 he did not sever his connexion with the Ministry, but filled the post of Secretary and Treasurer to Queen Mary's Hospital, Roehampton—an institution in which he had always taken the greatest interest, and for whose efficiency he was largely responsible. He finally retired in 1942, and spent most of his time at his home in Balcombe Forest.

He was a Knight of Grace of the Order of St. John of Jerusalem and an Honorary Fellow of University College Hospital. On his retirement from the Ministry of Pensions he was appointed consulting physician to that Department.

D. C. RAYNER, Ch.M., F.R.C.S., F.R.C.O.G.

We regret to announce that Emeritus Professor D. C. Rayner, who held the chair of obstetrics in the University of Bristol for six years, died in a Clifton nursing home on Oct. 21, aged 80. He still saw some patients until he himself became ill a short time ago.

David Charles Rayner was a student of the Bristol Medical School, and took the M.R.C.S., L.R.C.P. diplomas in 1892. He obtained the F.R.C.S. in 1896, became an original Fellow of the Royal College of Obstetricians and Gynaecologists in 1929, and received the Ch.M. degree from Bristol University in 1930. After graduating he worked for a time in the physiological laboratories, and then joined the staff of the Bristol Maternity Hospital. He was appointed assistant obstetric physician to the Bristol General Hospital, and reached the senior staff in 1923. He became director of clinical obstetrics in the University of Bristol in 1925, a year before his election as professor of obstetrics, and on his retirement from the chair at the end of 1932 he was made emeritus professor. He was for some years an examiner for the Central Midwives Board for England and Wales, and examiner in obstetrics for the University of Wales. At the Annual Meeting of the British Medical Association held at Bath in 1925 he served as vice-president of the Section of Obstetrics and Gynaecology, and he was also a past-president of the Bristol Medico-Chirurgical Society. He remained a member of the B.M.A. from 1894 until the time of his death. Prof. Rayner's published writings appeared in the *Lancet* (on rupture of the uterus in a case of normal labour), the *Birmingham Medical Record* (on puerperal sepsis), and the *Bristol Medico-Chirurgical Journal* (on the relation of gynaecology to the glands of internal secretion).

M. C. writes: Ex-students and nurses of the Bristol General Hospital will have read with distress of the loss of their old friend "Charlie Rayner." No man among the honorary staff won a greater measure of affectionate regard. His retiring and diffident manner, his unvarying kindness, courtesy, and charm, were coupled with considerable professional skill and experience. His modesty was quite disproportionate, but it failed to stem the growth of an enormous consulting practice. His services were freely available to all and sundry, at any hour of day or night. Not only was he unmercenary, but his generosity, or perhaps shyness, seemed often to prevent him from sending accounts even to the wealthiest of his patients.

Charlie appeared to have no hobbies or interests apart from his job, and when at home he lived with extreme bachelor simplicity and quietude, cared for by his devoted sister. Yet he was the friend of all, and no one in the West of England ever thought or spoke of him except in terms of the greatest warmth.

Universities and Colleges

UNIVERSITY OF OXFORD

In a Congregation held on Oct. 18 the following medical degrees were conferred:

D.M.—*W. E. Henley.

B.M., B.CH.—I. G. Waugh, H. R. Smart, T. W. Price, *V. J. K. Wright *E. L. N. Shoeten-Sack.

* In absence.

UNIVERSITY OF CAMBRIDGE

At a Congregation held on Oct. 19 the following medical degrees were conferred, all by proxy:

M.B., B.CHIR.—R. S. Lewis, J. A. R. Debenham, J. A. Rycroft, J. E. M. Whitehead, J. M. Cliff, E. D. Forster.

M.B.—W. A. Fell.

ROYAL COLLEGE OF PHYSICIANS OF LONDON

At a quarterly Comitia of the College held on Oct. 25, with the President, Lord Moran, in the chair, Dr. E. Bellingham Smith, Prof. A. W. M. Ellis, Prof. J. C. Bramwell, Dr. J. L. Livingstone, and Dr. E. R. Boland were elected Councillors.

The following were elected representatives of the College: Dr. H. E. A. Boldero on the committee of management of the Conjoint Board, Sir Comyns Berkeley on the Central Midwives Board, and Sir Francis Fraser on the Poisons Board.

The President announced the award of the Jenks Memorial Scholarship to J. C. Camac, late of Epsom College, and the Gilbert Blane Gold Medal to Surg. Lieut.-Cmdr. F. P. Ellis, M.B., R.N. Dr. R. E. Lane was appointed Milroy Lecturer for 1947.

The Comitia of the College endorsed the unanimous recommendation of its Council that the present interests of the College would best be served by remaining in its present premises. In coming to this decision the College has had the benefit of the advice of a panel of experts.

Dr. W. Russell Brain will deliver the Bradshaw Lecture on "Speech and Handedness" on Thursday, Nov. 8, at 2.30 p.m.

Membership

The following, having satisfied the Censors' Board, were elected to the Membership of the College:

Ailsa Bannerman, L.R.C.P., G. A. Copping, M.D., Lieut.-Col., R.C.A.M.C., G. D. Daruvala, M.D., C. E. Davies, B.M., A. P. Fletcher, M.B., Surg. Lieut., R.N.V.R., J. E. Francis, M.D., W. Ganado, M.D., W. W. Gooddy, M.B., Capt., R.A.M.C., S. J. M. Goulston, *M.C.*, M.B., Major, G. I. C. Ingram, M.B., A. J. Kerwin, M.D., Squad. Ldr. R.C.A.F., F. J. D. Knights, M.D., C. A. Leeson, M.B., P. F. Lucas, M.B., M. B. McIlroy, M.B., W. E. Mahon, L.R.C.P, J. A. W. Miller, M.B., Major, R.A.M.C., F. E. E. Sargent, M.D., D. Shiers, M.B., A. J. Shillitoe, M.B., J. McN. Tainsh, M.B.,

S. M. Talaat, L.R.C.P., E. C. Turton, M.B., P. Venables, M.B., D. R. Wilkie, M.D., H. P. Williams, L.R.C.P., Major, R.A.M.C.

Licences

Licences to practise were conferred upon the following 184 candidates (including 29 women) who had passed the Final Examination in Medicine, Surgery, and Midwifery of the Conjoint Board and who have complied with the necessary by-laws:

F. Alberts, R. C. Allison, Daphne S. A. Anderson, G. J. E. Ansell, E. R. Arnold, Lenorah M. Attkins, G. M. Bailey, Joan R. K. Bastable, J. G. Bearn, T. R. Bennett, F. M. Benton, M. Blackwell, Stella Booth, Camilla B. P. Bosanquet, Lesley M. McL. Bowen, H. L. Braterman, N. Brodie, D. E. St. J. Burrowes, J. P. Bush, I. Butler, N. J. Caldwell, Margaret Capra, C. L. Casimir, D. A. Chandler, D. J. Chapman, J. Clarke-Goldthorpe, J. P. Clayton, D. Cockcroft, N. C. Connell, D. E. Cullington, R. Davidson, R. H. Davidson, E. C. Davies, Elizabeth E. Davies, E. J. Ll. Davies, N. N. Davies, S. Davis, D. A. Dawson, C. H. de Boer, R. A. Denham, A. L. de Silva, D. C. de Ville, A. G. Dingley, E. M. C. Dunlop, A. L. T. Easton, A. McK. Elliott, E. Ellis, R. H. Ellis, R. F. Ewing, A. Fernandez, J. Fifield, M. L. H. Flindt, K. J. R. Ford, G. Forrester, W. S. Foster, A. E. Fyfe, G. F. J. Goddard, B. Gordon, C. W. Graham-Stewart, M. Grant, J. S. B. Greenfield, R. E. Gruchy, Tatiana P. Guercken, R. J. H. Guy, D. Hacking, H. M. Halle, Audrey Hanson, M. J. Harman, R. P. Harwood, A. G. Hayter, A. G. S. Heathcote, Mary Helmer, M. J. T. Hewetson, P. H. Hewitt, C. Hougie, Betty E. Howarth, D. E. Howells, C. H. A. Hoy, D. Hull, E. C. Hutchinson, M. S. R. Hutt, J. A. Hyde, C. C. Jackman, D. W. James, J. B. James, R. H. F. James, J. P. Janvrin, H. Jasowitz, P. M. Jeavons, F. F. Jerichower, D. J. B. Johnston, D. E. E. Jones, P. M. P. Jones, W. J. R. Jones, W. R. Juckes, H. T. Kay, H. E. M. Kay, Catherine M. R. Kirkpatrick, J. M. Kodicek, P. B. Kunkler, Stephanie A. Laing, H. A. Lane, J. G. Latimer, V. M. Leveaux, V. B. Levison, Helen M. Littler, Lilwen E. Lloyd, W. H. Lonsdale, J. D. Lucy, Joan V. Macdonald, R. C. McGregor, C. McIver, J. McMillan, P. N. Magee, J. E. Marrett, Margaret L. V. Matthews, M. Mattinson, W. G. Miln, M. Mir-Fakhrai, W. T. S. Moore, T. H. Morgan, D. R. Murley, R. R. W. Nichols, W. Niman, D. E. Oakley, Mora A. C. O'Hanlon, D. O'Keeffe, Liliane Parkinson, Deirdre Paulley, J. P. Penson, I. M. Perkins, P. J. Preston, A. H. C. Ratliff, J. W. T. Redfearn, P. A. Reed, N. C. Rees, Rosemary J. Reynolds, L. F. Richards, Rachel Richards, K. E. Rimmington, P. A. Ring, K. B. Roberts, J. O. Robinson, N. Rosedale, D. E. Rowlands, J. T. Rowling, C. M. Ruben, A. J. Rundle, Christine E. Sandford, G. A. Sedee, S. Seed, J. D. F. Shaw, D. A. Sherman, C. Shiers, Christine M. Singer, C. J. Stevenson, W. M. B. Strangeways, G. S. Tapsall, T. Taylor, H. G. Thomas, Peggy Thomas, J. M. Thompson, B. T. R. Thornton, Phyllida M. M. Thornton, W. R. R. Thursfield, J. V. Thurston, M. Tobias, D. G. L. Trust, F. T. G. Tuffnell, J. C. L. Wade, R. J. Walsh, D. A. Watkins, Mary Weston, J. A. Wheeler-Bennett, L. R. Whittaker, G. H. Whittle, W. B. Whowell, J. B. Wild, C. B. Williams, R. L. Wills, W. H. D. Wince, D. L. Woolf, K. A. A. Wray, Joan D. Wrigley.

Diplomas

Diplomas in Child Health were granted, jointly with the Royal College of Surgeons of England, to the 35 successful candidates whose names were published in the report of the meeting of the Royal College of Surgeons of England in the *Journal* of Oct. 27 (p. 588).

Diplomas in Ophthalmic Medicine and Surgery, in Medical Radiology, and in Physical Medicine were granted, jointly with the Royal College of Surgeons of England, to the following successful candidates:

OPHTHALMIC MEDICINE AND SURGERY.—D. Ainslie, F. J. Damato, A. J. Elliot, H. C. Kodilinye, J. M. Loftus, P. J. McNicholas, L. H. G. Moore, J. C. Mustardé, T. H. Negus, A. K. Pittman, D. Shorten, R. Vaughan-Jones.

MEDICAL RADIOLOGY.—R. A. Andrews, K. C. Falkner, R. M. Hall, T. M. Young.

PHYSICAL MEDICINE.—F. J. Bach, E. J. Crisp.

Medical Notes in Parliament

Bread and Nutrition

In the House of Lords on Oct. 24 Lord HANKEY moved that the health of the population should be the guiding principle governing the Government's nutritional policy, and that in the case of bread the health of the consumer should be the primary factor and milling and other interests should be developed in harmony with this policy. He said the debate on bread which had been initiated by Lord Teviot on Feb. 28 had aroused remarkable interest. The leading article on it in the *British Medical Journal* headed "The Political Loaf" [March 17, p. 372] had caused many a chuckle. Lord Teviot in that debate had secured an undertaking that if the Government had been found wrong in reducing the extraction of flour to 80% it would go back to 82½%. A second undertaking was that the Government would not reduce the rate below 80% until it was satisfied that this change would not be detrimental to nutrition. Lord Hankey said that in the subsequent eight months figures and facts had been published which suggested that the Government was wrong and ought to go back to 82½%, or better still to 85%. Figures supporting that contention were based on the seventh report of the Scientific Adviser's Division, Ministry of Food, checked by a memorandum on nutritive values of wartime foods which had been published by the Medical Research Council.

The present 80% flour showed no marked difference from the 85% flour of Lord Woolton in the figures for proteins, fats, carbohydrates, and calories. But the 85% flour contained a more valuable assortment of proteins, and their loss could not be stated in figures or corrected by enrichment or fortification. For the protective elements, which research had shown to be vital to health, the story was worse. The present 80% flour showed a loss of 10.2% in vitamin B compared with the 82% flour and 19.2% compared with the 85% flour; riboflavin showed a loss of 20% compared with last autumn's flour and 38½% compared with Lord Woolton's flour; nicotinic acid had a loss of 8.3% compared with the former but only 2½% compared with the latter. Iron in the present flour was reduced by 16½% compared with last autumn's flour and 21.7% compared with Lord Woolton's flour. That loss must be taken seriously because reduction in anaemia followed the introduction of the 85% flour. Other substances in wheat were removed progressively in passing from a whole wheat to a 75% flour. These unknown substances could be demonstrated by animal experiments to be nutritionally valuable. Obviously the millers could only put back what they knew they had taken out. Useful bran was also taken from the loaf. The 85% bread had been recommended all through the war as an optimum loaf by the Medical Research Council. The net result of the change involved the risk of an increase in anaemia, constipation, and consequential troubles.

A report on health and nutrition in the Channel Islands showed that the extraction level during the German occupation was practically 100% and that the great majority of people came to like the loaf. The medical profession of Jersey and Guernsey regretted its disappearance and its replacement by white bread when the relieving Forces arrived. While the 100% loaf was consumed the incidence of appendicitis, colds, and new cases of peptic ulcer was believed to have fallen considerably. In Jersey there had been no influenza epidemic. The first effect of the 100% loaf had been looseness of the bowels, sometimes severe, but after three months the symptoms abated and constipation, which before the occupation had been one of the commonest complaints, almost entirely disappeared. The investigators found nothing in Jersey approaching widespread undernutrition and were much impressed with the excellent condition of the teeth of the children. Lord Hankey added that vegetables had been unrationed and abundant during the occupation and were a staple food. Britain ought to go back to 82½ or 85%, and he asked the Government to publish the opinion of its scientific advisers.

NATURAL VITAMINS VERSUS SYNTHETIC

Lord HORDER, supporting the motion, said that since the debate on Feb. 28 a conference on the post-war loaf had been attended by representatives of the Ministry of Health, the Ministry of Agriculture, the Department of Health for Scotland, the Medical Research Council, the milling and baking industries, and flour importers. That conference agreed that three essential token nutrients could be specified as present in the wheat berry; that these could be assayed without difficulty and determined by the ordinary analyst; and that a minimum quantity of each of these should be present if bread was to remain the main contributory factor in the nation's health. Therefore the Government would have a basis on which it could make regulations requiring the minimum amounts of these substances to be present in flour, assuming that the Government decided to continue to regulate the character of flour.

The Chairman of the Food and Nutrition Board of the U.S.A. National Research Council reported that synthetic vitamins and vitamin concentrates were expedients which could not form the basis for a sound nutrition programme. The conference had left this question of the source of the token nutrients open for further research, but unanimously considered that in the meantime the Government should stick to the 80% extraction because it had coincided with such good health in the nation and could give the minimum quantities of the essential nutrients. Whether it did give them in the hands of a section of the milling industry could be judged only by analysis of bread obtained here and there in the country. There was no strict relation between the nutritive quality of flour and the extraction rate. Present knowledge of how these nutrients were distributed in the wheat grown was very recent, more of months than of years, but it had been confirmed. This knowledge permitted an improvement of milling to such an extent that they now knew at which part of the milling process the results should not be thrown away or even given to pigs and poultry. By the technique of milling they could direct into the flour the things they really required. The coarse fibre of bran could be diverted elsewhere and the loaf thereby made whiter and more acceptable to the average citizen.

Lord ADDISON agreed with the principle of the resolution that the health of the population should guide the nutritional policy of the Government. This country owed a debt to the Ministry of Food for emphasizing the importance of nutritional policy as underlying supply policy. The Government hoped to keep the benefits which had already arisen from that policy. It accepted the necessity for continuance of the Ministry of Food. Bread was not the only food to which the Ministry of Food had added advantageous materials: margarine had been greatly improved. He hoped the country would become accustomed to regard the existence of a Ministry of Food, performing these and other functions, as an essential part of our national economy.

He accepted the suggestion that the Government should publish the report of the conference on the post-war loaf. When that was done the discussion could be conducted on a higher level because it had hitherto been encumbered by guesswork. He noticed from the report that riboflavin was decidedly less in quantity in the 80% extraction than in the higher extraction. That was not of itself an objection to the 80% flour, because riboflavin was normally taken in other foods. He was authorized by the Minister of Food to say that he would give every help in furthering the researches which the conference recommended. The conference had unanimously suggested that in the meantime the present national flour should be maintained with the improvements brought about by the latest improved methods of milling. The Government proposed to accept that recommendation.

Lord **Teviot** said that in the last few years many of the old-fashioned stone-grinding mills had applied for licences to start again, but only a very small number had been granted. There should be an opportunity for restarting these mills.

Public Preference ?

Lord **Glentanar** said he was assured by an expert that the extraction to-day was no higher than 78%. He suggested that millers and bakers should have every opportunity to supply wholemeal bread and that white flour should be provided in small quantities for special purposes, but rationed if necessary. Lord **Llewellin**, speaking of the work done on the extraction rate of flour by the Cereals Research Station at St. Albans, said investigation there had proved that vitamin B_1 and most of the others were highly concentrated in part of the wheat germ, and that this fraction of the wheat could be segregated during milling to ensure that the great part of it went into the flour. When the extraction rate was reduced to 82½% there was a technical process in the mills to ensure that the necessary part of the germ reached the flour and did not go into the offal. It was no good towards the end of a war holding on too long to a kind of bread which the people did not like; a lot of manual workers were not enamoured of high-extraction flour. According to reports made to him when he was Minister of Food there had been an appreciable falling off in nutritional value when an 80% extraction was introduced, taking into account that other things besides bread were provided. Undoubtedly the 80% flour kept better, and the Royal Navy had insisted throughout the war on white flour for every ship commissioned for sea service. With the 85% extraction flour there had been a waste of bread.

Lord **Bledisloe** said he lived among miners and wondered whether the difficulties in securing adequate output of coal were not to some extent due to the fact that the miners preferred white bread and lean bacon. He affirmed that since the last debate on the subject in the House there had been no authoritative medical testimony in favour of a white loaf bereft of its protein, its fat, its iron, its calcium, and its vitamin B. It was the more necessary that bread should not be robbed because the present supply of whole milk was inadequate and would remain so for a considerable time.

The House agreed to Lord Hankey's motion.

Shortage of Nurses

On Oct. 25 Mr. **Bevan** announced that according to returns submitted to Mr. Isaacs there were on June 30, 1945, vacancies for about 30,000 nurses of all grades in hospitals and allied institutions, including nursing homes, in Great Britain. He added that he was consulting the Minister of Labour and the organizations principally concerned on the whole nursing position and hoped to make a full statement in two or three weeks. Arrangements were being made whereby women who are willing and suitable to be trained for the nursing profession might be released from the Forces in Class B.

Earl **Winterton** asked the Minister of Health to reconsider the regulation whereby former V.A.D.s and auxiliary nurses wishing to qualify as State-registered nurses would be exempted only from six months of their four years' training. Mr. **Bevan** replied that this was primarily a matter for the General Nursing Council, who decided after full consideration and discussion that the remission to be allowed in suitable cases should not exceed six months, thus reducing the minimum period of training from three to two and a half years. He had agreed to approve a rule to that effect.

Food of Diabetic and Tuberculous Persons.—Sir **Ben Smith** said on Oct. 10 that he was advised that the present allowances of foodstuffs for diabetic and tuberculous patients were adequate for their needs. He could only allow them extra eggs at the expense of other members of the community, some of whom suffered from complaints for which eggs were a necessity. During the present general shortage of foodstuffs he could not provide diabetic and tuberculous patients with extra eggs prescribed for them by their own doctor.

Health Insurance Benefit.—On Oct. 11 Mr. **Beechman** asked the Minister of National Insurance whether, in view of the delay before the passing into law of a comprehensive scheme of national insurance, he would forthwith introduce measures to bring the rate of sickness benefit into conformity with unemployment and other benefits, and extend to all cases of sickness provision for dependants. Mr. **James Griffiths** said that partial legislation on this matter in advance of the main insurance measure would be unsatisfactory. The Government intended so to frame the main legislation that the earliest practicable opportunity could be taken of bringing into effect, as part of a general plan, improvements in rates and conditions of health insurance benefit.

Mortality from Infectious Diseases.—Mr. **Bevan** has furnished the following table for England and Wales:

Death Rates per Million living under the Age of 15 Years

Cause	1940	1941	1942	1943	1944*
Scarlet fever	12	11	9	11	9
Diphtheria	266	280	192	134	92
Whooping-cough ..	78	279	94	129	121
Measles	95	128	53	86	28

* Rates for 1944 are provisional.

Notes in Brief

The possibility of treating Service tuberculosis patients in Service hospitals or Service wings of civilian sanatoria is being examined with a view to minimizing any delay between diagnosis and the institution of appropriate treatment.

In the British zone in Germany the minimum food value of all displaced persons is 2,000 calories per person per day.

The Ministry of Supply is the wartime production authority for *x*-ray equipment and accessories. The post-war position is under consideration, and no consultations with the industry have yet taken place.

Dr. Summerskill, in reply to a question to the Minister of Food, said on Oct. 18 that existing arrangements for supplying dried bananas to patients with coeliac disease should not cause difficulty or delay.

Correction.—The statement on release of students in Medical Notes in Parliament (Oct. 27, p. 589) contains a misprint; students eligible for release in Class B are those in groups 1–49, and not 1–19 as stated.

Medical News

The Council of the Royal Society of Medicine proposes to create a Section of Endocrinology. The 50th anniversary of the discovery of *x* rays will be celebrated by the Section of Radiology at a meeting on Thursday, Nov. 8, at 4.30 p.m., under the chairmanship of Lord Horder, and, at 8 p.m., there will be a reception and entertainment.

Dr. J. M. Alston, pathologist to the Archway Group Laboratory (L.C.C.), will lecture on the scope of penicillin therapy to the Association of Austrian Doctors in Great Britain on Nov. 8 at 6 p.m., at 69, Greencroft Gardens, N.W.6 (near Finchley Road Station). Guests will be welcome.

The Food Education Society (29, Gordon Square, W.C.) has arranged a public lecture on "Food and Behaviour," to be given by Dr. E. A. Hamilton Pearson at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, W.C., on Thursday, Nov. 15, at 3 p.m.

A meeting of the Tuberculosis Association will be held at 26, Portland Place, W., on Friday, Nov. 16. Papers will be read, at 4.45 p.m., by Prof. G. Selby Wilson on "Bovine Infection and Disease" and, at 5.50 p.m., by Dr. Kalman Mann on "Incidence of Primary and Haematogenous Lung Lesions in Skeletal Tuberculosis." At 8 p.m. there will be a discussion on "Prognosis and Treatment of Combined Tuberculosis," to be opened by Dr. Harley Stevens, Mr. G. R. Girdlestone, and Dr. F. S. Hawkins.

A meeting of the Society of Public Analysts and Other Analytical Chemists will be held at the Chemical Society's rooms (Burlington House, Piccadilly, W.) on Wednesday, Nov. 7, at 6 p.m., when the following papers will be presented and discussed: "The Determination of Carotene and Vitamin A in Butter and Margarine," by Mr. T. W. Goodwin and Prof. R. A. Morton, and "A Photo-electric Method of Assaying Vitamin A in Margarine," by Messrs. J. L. Bowen, N. T. Gridgeman, and G. F. Longman.

Dr. John Scott Clark has been released from internment in Japanese hands.

David Paton Cuthbertson, M.D., D.Sc., has been appointed director of the Rowett Research Institute at Aberdeen in succession to Sir John Boyd Orr. Dr. Cuthbertson, who is Grieve Lecturer in physiological chemistry at Glasgow University, was educated at Glasgow and Leipzig Universities, and was previously lecturer in pathological biochemistry.

Prof. E. C. Dodds, M.D., F.R.S., director of the Courtauld Institute of Biochemistry at Middlesex Hospital and a member of the Grand Council of the British Empire Cancer Campaign, is visiting Norway, Sweden, Denmark, and Finland, under the auspices of the British Council, to lecture on cancer research and biological and medical subjects.

Field-Marshal Sir Bernard Montgomery, in an address to the Royal United Services Institution in London, has paid a high tribute to the medical organization of the Army, which, he said, had almost halved sickness among the troops compared with the war of 1914–18. As the B.L.A. swept through Germany, liberating prison camps such as Belsen, where thousands were dying of typhus, only 25 British troops contracted the disease, and none died of it. This was due to preventive inoculations and to the adequate supply of D.D.T. Through the use of penicillin many men who would have been permanent invalids after the last war were fit and ready to go back to the line within a month of being wounded. Doctors, the Field-Marshal said, were prepared to lay fifteen to one that once a man got into their hands, whatever his injury, they would save his life and restore him to health. It was a fine thing that these odds were achieved with a handsome margin.

Mr. Angus Rhodes, J.P., of Bradford, has generously founded a research scholarship to be associated with the Regional Radium Institute, Bradford. It is intended that the research should be of a clinical nature into an aspect of the cancer problem to be decided by the Trustees. These include the chairman of the Board of Management of the Bradford Royal Infirmary, the Town Clerk of Bradford, the donor and his solicitor, with the Medical Director of the Radium Institute as scientific adviser. The scholarship fund was established soon after the outbreak of war, but no scholar has yet been appointed. It is intended to advertise the post as soon as conditions permit, but in the meantime the Trustees feel that the existence of this scholarship might be of interest to medical practitioners both at home and in the Forces over-seas.

Dr. A. F. Foster-Carter has been appointed temporary medical superintendent of Brompton Hospital Sanatorium, Frimley.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* infectious diseases were more prevalent. The rises over the last week's totals included 166 for scarlet fever, 86 for diphtheria, 79 for measles, 79 for dysentery, and 61 for whooping-cough.

Diphtheria notifications equalled the greatest weekly total of the present year, the largest increases within the counties being as follows: Yorks West Riding 26, Lancashire 15, Glamorganshire 13, London 11. The rise in measles notifications suggests that the minimum level, after the epidemic which reached its maximum with 25,507 cases during the twelfth week of this year, has been passed. The rise was due mainly to London and the south-east and south-west, where altogether 58 more cases were notified than in the preceding week.

There were fresh outbreaks of dysentery in Kent (19), Staffordshire (17), and Durham (10). Lancashire recorded 55 more cases than last week, the chief centres of infection being Blackburn R.D. 48, Liverpool C.B. 24, and Manchester C.B. 12. The other large returns were London 40, Glamorganshire 18, Yorks North Riding 16, Surrey 14, Middlesex 11.

In *Scotland* there were 24 fewer notifications of dysentery, and 11 fewer of diphtheria, but 30 more of acute primary pneumonia, and 23 more of scarlet fever. Dysentery was less prevalent in the south-east and the west, but was more frequent in the other areas; the chief falls were in Glasgow, from 66 to 39, and Edinburgh, from 19 to 11.

In *Eire* there were 24 fewer cases of whooping-cough than last weeek, 9 fewer of diphtheria, and 8 fewer of diarrhoea and enteritis. Thirty-four of the 36 cases of whooping-cough, and 45 of the 54 cases of diarrhoea and enteritis, were notified in Dublin C.B.

In *Northern Ireland*, owing to sporadic cases, the notifications of diphtheria rose by 9.

Week Ending October 20

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,768, whooping-cough 1,087, diphtheria 604, measles 441, acute pneumonia 518, cerebrospinal fever 39, acute poliomyelitis 28, dysentery 284, paratyphoid 7, typhoid 5.

No. 41

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Oct. 13.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1945					1944 (Corresponding Week)

Rate per 1,000 total births (including stillborn)								28		

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to movements of population, birth and death rates for Northern Ireland are still not available.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Aitiology Westcent, London.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London.*

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Westcent, London.*

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Alcoholism

Q.—*A patient suffers from drinking bouts, which last for a month or so, and in the intervals between he does not touch alcohol. The condition is hereditary, and appears to follow the male or the female line in the family. The bout begins by someone asking the patient to have a drink; the patient thereafter takes to his own room, abandons all thought of work, refuses to see anyone, even his wife, refuses normal food and consumes only alcohol. After three to four weeks he becomes so "soaked" that he is physically unable to take as much alcohol as he would like and he slowly emerges from the bout and resumes a normal mode of life. Is there any treatment to prevent the onset of attacks, apart from rigid abstinence from alcohol? I can find no literature on this subject.*

A.—A distinction should be made between ordinary "drunkenness," persistent drinking because one wants to, and "alcoholism"—a term we may reserve for such attacks as the one described, which are usually compulsive in nature, recurrent and periodic and not persistent, and in which during the intervals the patient may be free from any desire for alcohol. A hidden physical predisposition is often present; cases in point being a mild duodenitis, producing the sense of craving, and a low blood sugar is another, the correction of which alone has been known to cure these cases. The toxicity of alcohol is also increased with a low B.P. On the psychological side such alcoholism must be regarded as a neurosis, and is an attempt to escape from life. It frequently occurs, therefore, in sensitive people (artistic and intellectual) who find adaptation to the world difficult. This may account for the "hereditary" aspect of the disorder. But the family history may also be due to transmission, not by heredity but by identification of the child with the parent—a very potent influence which we have known to cause alcoholism as it does other character traits good and bad. This may be the reason why in this case the alcoholism follows either the male or the female line, since the boy identifies himself with the father, the girl with her mother.

But the tendency to escape from life is not merely due to constitutional sensitiveness, but to early environmental conditions and a sense of insecurity in childhood, which again is more likely to occur if a parent is alcoholic. The question still remains why the need to escape takes the form of alcoholism. This may be accidental, but on analysis it is often found to date back to "oral eroticism," the resort to drinking indulged in, as in infancy at the breast, not merely as a sensuous pleasure but as a comfort and solace. In other words, it is a regression to infancy due to fixation and arrest of development. In these cases deep investigation by analysis into the unconscious causes may be necessary for a radical cure. But temporary (and sometimes permanent) cure may come about by reconditioning the alcoholism by giving the patient nothing but his favourite alcohol to drink, and an injection of apomorphine to make him sick after each drink; but complete abstinence from alcohol thereafter is necessary.

As for literature I may refer the questioner to Dr. Carver's article in the *British Journal of Inebriety* (July–October, 1945), and the references there mentioned.

Sulphonamide Allergy

Q.—*What are the explanation and treatment of skin sensitivity following the local application of the sulphonamide group of drugs, and revealing itself on exposure to sunlight?*

A.—The mechanism of drug allergy is conceived as follows. The drug, or a breakdown product of the drug, combines with protein in the tissues or body fluids to form a conjugated protein. The body treats this conjugated protein as if it were foreign protein and reacts to it by the formation of antibodies. The stage is thus set for an allergic reaction with any traces of sulphonamide-protein remaining in the tissues and whenever the patient comes in contact with the drug again.

The explanation of sensitivity to sunlight in sulphonamide-sensitive patients is more controversial. It has been suggested that porphyrins are formed as a result of the toxic action of the sulphonamide, and that they sensitize the skin of the patient to ultra-violet light, in the same way as it can be sensitized by other fluorescent substances, such as eosin. This seems unlikely owing to the long duration of photosensitivity. It is more probable that the antibody formed as a specific response to the sulphonamide-protein also reacts in a non-specific way with the altered protein produced by the action of ultra-violet rays on the skin. As both proteins are probably altered skin protein, they may well be antigenically very similar. In the same way a flare-up may occur at the site of a previous tuberculin reaction on exposure to ultra-violet light, or a dermatitis due to allergy to primula may flare up if the hands are repeatedly exposed to antiseptic solutions such as bichloride of mercury or phenol.

Desensitization of patients who suffer from skin sensitivity may be attempted by giving small doses of the relevant sulphonamide by mouth—e.g., 0.1 g. four-hourly, increasing it until a dose of 1.0 g. can be tolerated without reaction. The procedure is not free from risk and requires extremely careful supervision (cf. Tate, B. C., and Klorfajn, I., *Lancet*, 1944, 2, 553).

Fat Atrophy and Insulin Injections

Q.—*I have been treating a diabetic with zinc-proteinate insulin. After about six months, during which she had remained practically sugar-free, it was found that at the sites of injection in the arms the tissues were disappearing, leaving a deforming concavity down to the bone. The insulin was changed to the ordinary variety A.B., but the atrophy of the tissues continued at other sites then used on the thighs. Can you advise me how this can be avoided?*

A.—The condition of fat atrophy which occurs at the site of the insulin injection is well known. It occurs in a small proportion of patients, and is due to some substance in the insulin solution to which the patient's tissues are sensitive. It is worth while trying whether one of the other two brands of insulin is less destructive to the subcutaneous tissues and, if so, using it. The protamine-zinc-insulins are no worse or better than the ordinary insulins for these patients. The best advice to give is to change the site of injection so that no one spot receives repeated injections. The front and sides of the thighs, the legs between the knee and ankle, the front of the abdomen and chest, the back, and the arms should all be used in turn. If this can be done the injury to the tissues will be much less and the subcutaneous tissues already damaged may slowly recover.

Nicotinic Acid for Chilblains

Q.—*I understand that favourable results in the prevention of chilblains have been claimed by the use of an intensive course of nicotinic acid taken early in the autumn—e.g., 450 mg. daily for 10 days. Is there any evidence for the claim, and, if so, what is the rationale?*

A.—I can see no rationale for the use of nicotinic acid for chilblains except that by causing flushing *temporarily* it improves the circulation. I should not expect the effect of taking an intensive course to be in any way lasting in this regard.

Infertility

Q.—*A female patient, aged 32, after having nine years' experience as a radiographer, became married eighteen months ago. When no conception had occurred after six months she submitted to an endometrial curettage. The pathological report was "anovular menstruation." Injections of serum gonadotrophin and chorionic gonadotrophin were prescribed, and five months later a second premenstrual endometrial curettage was performed. This time the report stated that secretory changes were occurring "in rather less than one-half of the cells." Gynaecological examination reveals no pathological condition other than a tendency to retroversion of the uterus. What are this woman's chances of becoming pregnant, and is her profession as a radiographer the possible cause of her sterility?*

A.—The facts indicate that during one menstrual cycle ovulation did not occur and that during another cycle, five months later, it did. It is hardly permissible to assume that anovular menstruation was a constant or frequent phenomenon before treatment, or that the gonadotrophin played any part in determining ovulation later.

It is quite impossible to give any sort of estimate of the chances for conception without knowing more of the case. Is there any information as to the fertility of the husband? Have other investigations—e.g., tubal patency tests—been carried out? Has the position of the uterus been corrected for trial? On the evidence it seems hardly justifiable to conclude that the infertility is due to a failure of ovulation; all other possible causes will need to be excluded first. The varying response of different areas of the endometrium ("irregular ripening") is an interesting observation, but it is by no means uncommon. It might mean defective action on the part of the corpus luteum, or a variable sensitivity on the part of the endometrial cells. However, the fact that any secretory change occurred does indicate the presence of functional corpus luteum tissue at the time.

If it is established that menstruation is nearly always anovular in this case, then it must be admitted that exposure to *x* rays over a long period may have damaged the follicular apparatus. Such an effect, however, is not necessarily permanent. Moreover, it remains only a possibility, for anovular menstruation frequently occurs without any apparent cause, and the usual precautions adopted by *x*-ray workers give adequate protection to the ovaries. It might be added that minimal doses of *x* rays are *reputed* to be stimulating to the ovaries.

Little's Disease

Q.—*What is considered to be the cause of Little's disease, and what is the outlook for a patient suffering from the condition?*

A.—The answer to this question is provided by R. M. Stewart (*Proc. roy. Soc. Med.*, 1942–3, **34**, 25), whose paper includes a review of the relevant literature. Briefly, there is no single cause. The commonest abnormality is a prenatal primary degeneration of the cerebral neurones, for which there are probably many causes. The outlook depends upon the severity of the motor disability and the presence or absence of mental defect. When the motor disability is not too severe, and mental development is good, slow improvement may be expected during the first ten years of life, but considerable residual difficulty in walking is inevitable in all but the mildest cases.

Iron and Thrombosis

Q.—*Could administration of iron—e.g., as ferrous sulphate—precipitate or predispose to cerebral thrombosis? One patient treated with iron for about ten days suddenly developed aphasia. Another, who persisted in taking iron for many years in spite of absence of anaemia, developed hemiplegia. These cases may be coincidental.*

A.—There is no evidence that iron favours thrombosis. Cerebral accidents sometimes occur in patients with arterial disease and anaemia, when the anaemia is repaired by liver or iron. This is presumably due to an increase of blood pressure and blood viscosity as a result of the rise in the red cell count and total red cell volume, and not to the iron or liver *per se*.

Heredity in Cleft Palate, Hare-lip, and Spina Bifida

Q.—*Are spina bifida, cleft palate, and hare-lip hereditary? Are parents with spina bifida occulta likely to have children with spina bifida?*

A.—Cleft palate and hare-lip undoubtedly have a strongly hereditary basis, though the story is not a simple one. It seems clear that a recessive gene is responsible in the great majority of instances, but not all individuals who possess the requisite genetic constitution suffer from the abnormality. Additional influences have to play their part before the defect can become manifest. One of these additional factors is sex, for boys are more commonly affected than girls. What other factors are involved is not known; they may be genetic or non-genetic. It may be that the double dose of the recessive factor makes the developing embryo unduly sensitive at critical periods to what would otherwise be unimportant variations in uterine environment. Perhaps a quarter to half of those bearing the double dose of the recessive gene develop the condition; but this is largely a guess. It is likely that the recessive gene responsible is not always the same, and it has been shown that one gene pair, sometimes responsible, is partially sex-linked. This discovery is very interesting academically, and in practice means that males tend to transmit to more of their male than of their female relatives, and vice versa. It would also appear that the partially sex-linked cases are especially severely affected. Some pedigrees make it likely that sometimes, though very rarely, inheritance may be dominant. If so, the dominant gene also is one which does not always express itself, so that the skipping of a generation is common.

Spina bifida is genetically more obscure, perhaps because it has not been studied so systematically. The great variation in expression and the occurrence of spina bifida occulta are obvious difficulties as regards investigation. No doubt, however, heredity is involved; it has been thought to be recessive. If so, the union of two persons both of whom had spina bifida occulta would in all probability greatly increase the chances of frankly affected offspring in the next generation.

LETTERS, NOTES, ETC.

Venereology

Dr. Robert Cook (University College, Dundee) writes: I have followed with great interest the correspondence on the word "venereology" by Brig. T. E. Osmond (Oct. 20, p. 556) and Lieut.-Col. H. Richards (Sept. 22, p. 414). Looked at from a very broad point of view certain diseases are connected with "love," and hence association with the goddess Venus is not altogether inappropriate. To discountenance any suggestion of male prejudice we may remark that Eros has his name already in well-established adjectival usage. A study of Smith's admirable *Classical Dictionary* suggests the goddess in her primitive form—Astarte.

> "Where are they, Cotytto or Venus,
> Astarte or Ashtaroth, where?"

I suggest "astartic diseases" and "astartology.". If a portmanteau word is wanted for a specialist in the three diseases, as a humble suggestion (constructive, I hope) why not the word "syphogossologist"?

Elongated Styloid Process Causing Symptoms in Throat

Mr. A. J. d'Abreu (Newtown, Waterford) writes: Early in February, 1926, a man aged 51 consulted me for discomfort on the left side of his neck and throat. On examination the left tonsil appeared large, globular in shape, and pushed out. Palpation revealed a bony structure, which could be traced by the finger towards the neck. It was slightly movable. Pre-operative diagnosis of the much-elongated styloid process of the temporal bone pressing on the tonsil was made. Under regional analgesia the tonsil was enucleated. The point of the styloid process was now easily felt. It was denuded of the fascia surrounding it, the process bared, and about an inch of it cut away with bone forceps. The chief difficulty of the operation was the huge tongue of the patient, who, however, was very co-operative, and the analgesia was perfect. No radiograph was then available; the other tonsil was also removed, but no styloid process was felt or any symptoms complained of on that side. Seen a few weeks afterwards, and again after some years, the patient was well pleased, for all symptoms had disappeared.

In Aid of the Grenfell Mission

In a year in which there will inevitably be many calls upon sympathy and generosity for the suffering in Europe we would nevertheless ask doctors to remember, even more generously than usual, the work of healing and of education and welfare that goes on continuously among the scattered poor population of Newfoundland and Labrador. The Grenfell Mission, whose hospitals and nursing stations in remote places are the only means of bringing help in times of distress to the people and whose schools provide the only education to be had by children in isolated settlements, needs funds urgently, and doctors can help by purchasing their Christmas cards from the Grenfell Association in this country. This year there are two attractive cards in colour, price 10d. each, a number in black and white, price 5d. each, and a pocket calendar, price 2d., postage extra. They may be obtained from the Grenfell Association at 66, Victoria Street, London, S.W.1, or at 21, Bothwell Street, Glasgow, C.2.

A Boarding School for Maladjusted Children

All who are concerned with the care of difficult and maladjusted children have recognized the need for hostels or (better) residential schools for some of such children where they can be not only taught but also treated by child-guidance experts. Among the problems of war evacuation was that of the care of "unmanageable" children, many of whom were orphans and backward. To meet this need the Friends Relief Services established a residential school at Chaigeley Manor. This was so successful that an effort is being made to continue the work in Cheshire in connexion with neighbouring child-guidance clinics. Although the new Education Act requires education authorities to make provision for maladjusted children, it is the custom in this country to leave the pioneer experimental work to voluntary effort, so that the best method may be discovered before the taxpayer shoulders the burden. Money is therefore needed to promote the Chaigeley venture, and we can be confident that the object is worthy of whole-hearted support. The address of the school is Thelwall, Lymm, Cheshire, and the office is at Friends' Meeting House, 6, Mount Street, Manchester, 2.

Messrs. H. K. Lewis and Co. are considering the extension of their lending library to include foreign medical and scientific books. To obtain information about the desire for such books a short questionary has been prepared for circulation to subscribers and others likely to be interested. Those who would like a copy of the form may have one on applying to 136, Gower Street, London, W.C.1.

BRITISH MEDICAL JOURNAL

LONDON SATURDAY NOVEMBER 10 1945

THE USE OF MICRO-ORGANISMS FOR THERAPEUTIC PURPOSES*

BY

Sir **HOWARD W. FLOREY**, M.D., Ph.D., F.R.S.

Professor of Pathology, University of Oxford

There can be no one in the whole history of surgery who more deserves commemoration than Lister, and to be asked to deliver a memorial lecture is at once a great honour and a somewhat heavy responsibility. I am not a surgeon, and it did not seem appropriate for me to lecture on an exclusively surgical subject, but as Lister in his own person combined great capacities as an experimentalist with an ability to make epoch-making innovations in surgery, I thought that to-day it might be permissible to treat of some of the scientific background which is becoming more and more important in the practice of surgery.

It may not be realized by all that Lister made some most important contributions to bacteriology—a subject which was to him of the greatest significance when he had grasped the bearing of Pasteur's observations on his own problem of "putrefaction." Lister's aim was essentially what is now called aseptic rather than antiseptic, his object being to exclude all organisms at operation, including those of the air, by means of chemical antiseptics. It is true that he used antiseptics in the treatment of established infections, but his main aim was the exclusion of pathogenic bacteria, which he at first conceived to be those floating in the air. I can imagine that Lister would be delighted to know that in the course of time some of these same organisms have been made to yield substances with almost ideal properties for the treatment and prevention of sepsis. It is a widespread idea that our knowledge of the existence of such substances is of recent origin, so I have thought it might be of interest to trace the development of this subject, partly to give a background against which to measure modern achievements and partly to help to orientate further work from both the biological and the more strictly surgical points of view.

Early Conception of Antibiosis

The antiseptic substances which we now know to be produced by many micro-organisms are beginning to be known as antibiotics. The word "antibiosis" was first used by Vuillemin in 1889. He wrote:

> "The lion that springs on its prey and the serpent that poisons the wound before devouring its victim are not considered to be parasites. There is nothing equivocal about it—one creature destroys the life of another in order to sustain its own, the first being entirely active and the second entirely passive; one is in unrestricted opposition to the life of the other. The condition is so simple that it has never been named, but instead of being examined in isolation it can be viewed as a factor in more complex phenomena. For simplicity we shall refer to it as *antibiosis*; the active participant will be the *antibiote*."

Marshall Ward blessed the word in 1899, and it has been frequently used since. The use of the word antibiotic for the actual chemical substances involved in bacterial antagonism was recently introduced by Waksman.

Just as Pasteur's conception of bacteria as the cause of disease was the starting-point of much of Lister's work so Pasteur, with his colleague Joubert, was the first to describe in 1887 the existence of this antibiosis affecting a disease-producing micro-organism. They were working on anthrax, and wrote:

> "Neutral or slightly alkaline urine is an excellent medium for the bacteria. If the urine is sterile and the culture pure the bacteria multiply so fast that in the course of a few hours their filaments fill the fluid with a downy felt. But if when the urine is inoculated with these bacteria an aerobic organism, for example one of the 'common bacteria,' is sown at the same time, the anthrax bacterium makes little or no growth and sooner or later dies out altogether. It is a remarkable thing that the same phenomenon is seen in the body even of those animals most susceptible to anthrax, leading to the astonishing result that anthrax bacteria can be introduced in profusion into an animal, which yet does not develop the disease; it is only necessary to add some 'common bacteria' at the same time to the liquid containing the suspension of anthrax bacteria. These facts perhaps justify the highest hopes for therapeutics."

Pasteur himself seems to have done no more work on this phenomenon, but in 1885 several papers of considerable interest appeared. The most important of these was by Babès, who demonstrated on solid as well as in liquid media that one organism can elaborate a substance which will stop the growth of another. He wrote that he had "studied experimentally the way in which bacteria of a known species produce chemical substances or modify the culture medium in such a way as to harm bacteria of other species. If the study of the mutual antagonisms of bacteria were sufficiently far advanced a disease caused by one bacterium could probably be treated by another." And later in his paper he said: "A further and wider study of this reciprocal action of bacteria may lead to new ideas in therapeutics." In this year, 1885, also appeared a paper by Catani, who opened with the words: "The known fact that certain bacteria can destroy other, even pathogenic, microbes if they come in contact with them in any way gave me the idea of exploring this procedure for the treatment of various infectious diseases." He took an organism which was called *Bacterium termo* (it appears to have been a mixture of species) and showed its lack of pathogenicity for animals. He then treated a patient suffering from severe tuberculosis by insufflating

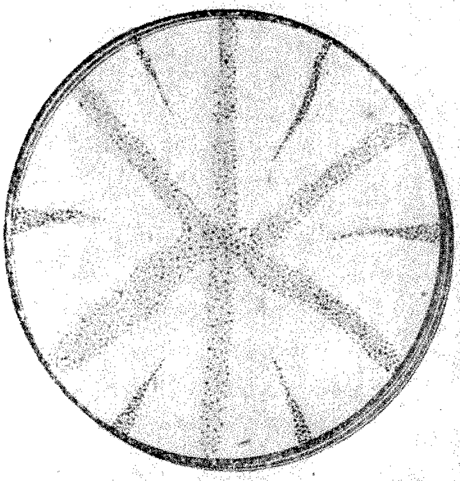

FIG. 1 (from Frost, 1904).—Drawing showing Garré's method of studying antagonism by means of alternate streaks. The large streaks of *Ps. fluorescens* were allowed to grow for 24 hours and then streaks of *Bact. typhosum* were made. These grew only where they were furthest from the streaks of *Ps. fluorescens*.

* The Lister Memorial Lecture, delivered at the Royal College of Surgeons of England, Oct. 11, 1945.

directly into the lungs by means of an atomizer a culture mixed with gelatin. The tubercle bacilli disappeared from the sputum and *Bact. termo* appeared in their place, while at the same time the patient's condition improved. He suggested that this method of bacteriotherapy might be applicable to infected surfaces. This, then, was the first example of the idea of replacing one organism by another less harmful—an idea which, we shall see, frequently recurs in succeeding years.

In 1887 an important bacteriological contribution was made by the Swiss, Garré. He introduced methods for the examination of bacterial antagonism which differ little from those in use at the present day. Fig. 1 is an illustration of one of Garré's methods which was given in a paper by Frost nearly 20 years later. In this the streaks of the antagonist and the organism to be antagonized are arranged alternately, radiating from the centre, but sometimes the streaks were put down parallel to one another at increasing distances. Garré wrote:

> "I inoculated on the untouched cooled [gelatin] plate alternate parallel strokes of *B. fluorescens* and *Staph. pyogenes*. This was carried out so that the distance between the inoculated strokes increased from 3 to 15 mm. *B. fluorescens* grew more quickly. Its products of secretion diffused into the surroundings and were completely inhibitory for the near-by staphylococcal inoculation. . . . It is thus not a question of overgrowth or crowding out of one by another quicker-growing species, as in a garden where luxuriantly growing weeds kill the delicate plants. It is also not due to the utilization of the available foodstuff by the more quickly growing organism, but it is a question of antagonism caused by the secretion of a specific, easily diffusible substance which is inhibitory to the growth of one species but completely ineffective against the species producing it."

He also had the idea of using this phenomenon in therapeutics.

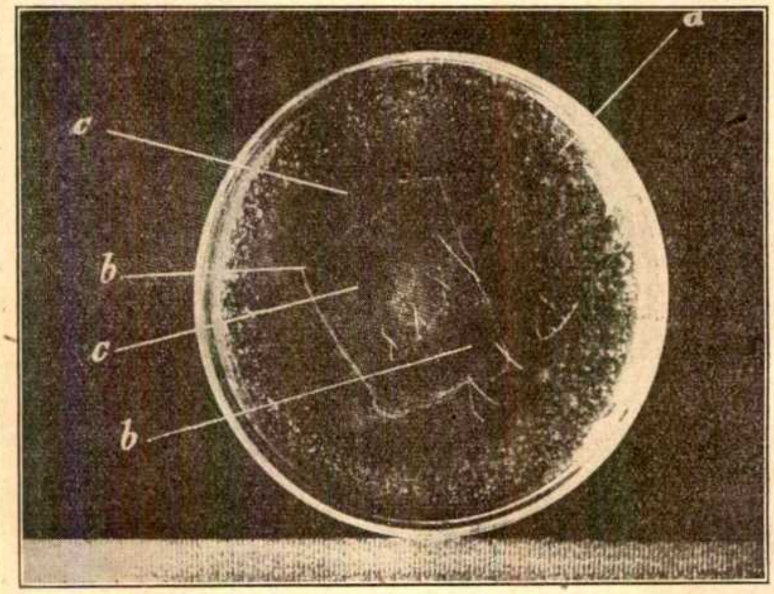

FIG. 2 (from Doehle's thesis, 1889).—A plate was poured with gelatin containing anthrax bacilli. On the surface was planted a square of *M. anthracotoxicus*. Surrounding this square is a zone in which no anthrax colonies have developed, owing to the diffusion of an inhibitory substance from the micrococcus.

There were other publications on the same subject about this time; but the work of Doehle, who published his thesis in 1889, is of outstanding interest, as it contains the earliest illustration of antibiotic action that I have encountered (Fig. 2). Doehle mixed anthrax bacilli with melted gelatin and poured the mixture into a dish and then planted in a square on the surface a certain micrococcus which he had isolated and called "*Micrococcus anthracotoxicus*." After incubation the square where the micrococcus had grown was surrounded by a clear zone in which the anthrax bacilli were completely inhibited. This technique and Garré's differ little, if at all, from those employed by some workers at the present day. Doehle hoped to use his organism for the protection of animals against infection by *B. anthracis*, but his results were indecisive.

Non-specific Immunity

While these clear-cut bacteriological observations had definitely shown that there were micro-organisms which produced substances harmful to the growth of some pathogenic bacteria another approach to bacteriotherapy was being made, which had as its basis the idea of a non-specific immunity produced by one type of organism against another. Clinicians had for long believed that an attack of erysipelas was beneficial in certain chronic infections, and in 1883 Fehleisen deliberately treated a case of lupus by injecting streptococci obtained from a patient with erysipelas. In 1887 Emmerich made observations on anthrax infection which showed that an injection of streptococci enabled a substantial proportion of rabbits to survive a subsequent dose of anthrax bacilli large enough to kill all the control animals. Moreover, the intravenous injection of streptococci into rabbits already showing "clinical" anthrax prevented the death of 60%. Emmerich demonstrated that there was no antagonism between the two organisms *in vitro* on the surface of a solid medium, so he ascribed his results to stimulation by the cocci of the body cells, which were then able to demolish the bacilli. This work was confirmed by several people, some of whom used other organisms than the streptococcus and in some cases killed the cultures before injection.

A paper by Bouchard in 1889 started work on another organism which still continues even at the present time. He published results showing that the inoculation of *Ps. pyocyanea* conferred a considerable degree of protection against *B. anthracis* infection in rabbits, though in guinea-pigs the results were not so good. This same organism was actually injected by Rumpf in 1893 for the treatment of typhoid fever in man, but the good results which he claimed were not confirmed by Kraus and Buswell (1894) or Presser (1895).

Local Application of Bacterial Products

During this period a number of authors contributed to the further accumulation of knowledge, but from a clinical point of view the observations of Honl and Bukovsky (1898) are of most interest. These Russian investigators described in enthusiastic terms the results of the local application of "proteins" from cultures of *Ps. pyocyanea*. They thought that they might accelerate the healing of ulcers by applying the proteins or products of micro-organisms isolated from the ulcers, but gave no details of how they made their preparation. They treated by local application more than a hundred infected ulcers of the leg and similar cases, some of which were so bad that amputation was under consideration, and they were very pleased with their results.

Unconnected with this work, Emmerich and Löw in 1899 introduced the first antibacterial extract into medicine. This extract, which they called pyocyanase, was capable of lysing suspensions of *B. anthracis in vitro* in a short time, and was also bactericidal to *Bact. typhosum*, *C. diphtheriae*, staphylococcus, and *P. pestis*. It was prepared from old cultures of *Ps. pyocyanea*. They performed therapeutic experiments on animals with the substance, but their views as to the rationale of the treatment are not by any means clear. Apparently they became confused between their knowledge of its antibiotic effect and their wish to bring it into line with the prevailing views on immunity.

Following Emmerich and Löw's work there was a remarkable outburst of energy both in the laboratory and in the clinic. Laboratory work fully confirmed that the extract was bactericidal, but controversy raged over the nature of the substance. Emmerich and Löw maintained that it was an enzyme (that is, a protein), while other workers found good evidence that it was a "lipoid" (that is, soluble in certain organic solvents) —a view which is confirmed by recent work.

A few years after the beginning of the century the idea of using it in the clinic by injection was replaced by that of using it as a local antiseptic. There can be no doubt that it was bactericidal, and Emmerich and Löw also thought that it was more harmful to bacteria than to animal cells. This important idea of differential toxicity, which so largely governs the choice of antiseptics to-day, must have been widespread at that time, for Escherich wrote in 1906: "The resumption of these endeavours first became possible when the march of science made known to us a substance which possessed a high bactericidal capacity without at the same time harming the tissues as do previously known antiseptics. This material is the bactericidal substance from the autolysis of bacteria, discovered by Emmerich and Löw." In 1913, in a review of the position, Sonnenberger echoed these views, for he wrote: "The use of pyocyanase as a therapeutic agent is based on exact theoretical considerations. These are backed by clear-cut experiments both *in vitro* and *in vivo*. Its harmlessness within the limits of its usual employment is well established. Its capacity for healing in a large number of diseases has been proved in the clinic. Pyocyanase may be considered an important addition to therapeutics. Its widespread use is recommended within the limits given in this work." This material was very extensively used in the clinic. Many papers deal with its employment as a local antiseptic in diphtheria both for acute cases and for carriers. Meningococcal carriers were also, it was claimed, successfully treated, and the suggestion was made that it might be useful as a prophylactic spray during epidemics. It was used for conjunctivitis and other eye infections, for injection into abscesses, for the treatment of infection of the accessory nasal sinuses and diseases of the mouth such as Vincent's angina. It was injected into the trachea and even injected intrathecally in cases of meningitis. Many of these procedures have their parallel in recent uses of penicillin. It was used in veterinary medicine for streptococcal mastitis by injecting it into the udder, much as gramicidin and penicillin are used at the present day, and in addition both chemical and pharmacological examinations on a considerable scale were done to determine its properties. Thus it can be said with some truth that there is little that has been done with penicillin which was not attempted with the earlier antibiotic so far as the means then available allowed.

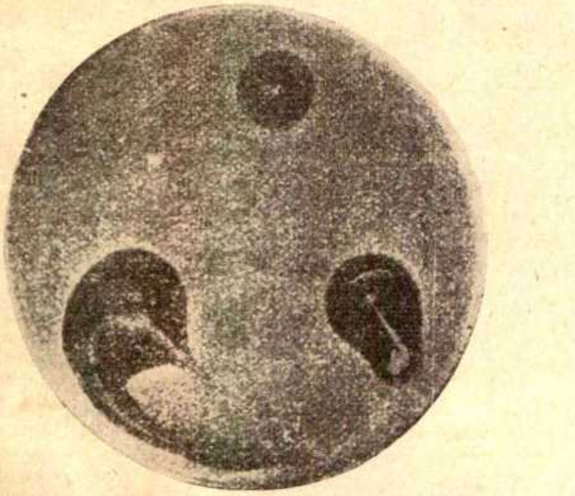

FIG. 3 (from Lode, 1903).—This shows a plate thickly sown with *M. tetragenus*. Colonies of an accidental air contaminant —a coccus—have been planted at three places, and around them are zones in which the growth of *M. tetragenus* is inhibited.

While this work was being actively pursued other investigations of great interest were recorded. In 1903 Lode wrote of an accidental contaminant he had found while preparing a plate of *M. tetragenus* for class demonstration purposes. This contaminating organism, which was a Gram-positive coccus, was subcultured and shown to produce a diffusible inhibitory substance (Fig. 3). It strongly inhibited anthrax bacilli and *Staph. aureus*, but not *Bact. coli* or Friedländer's bacillus. Lode did considerable work on the production of the antibiotic in fluid cultures, and showed that it was bactericidal. It was not an enzyme, though it was thermolabile, being inactivated slowly by heat. It could be dried by vacuum distillation and was soluble in alcohol but not in ether. Neither the micro-organism nor its metabolic products were toxic to animals, but unfortunately in artificially produced infection in mice the product had no chemotherapeutic effect. Nevertheless, this work is remarkable for the comprehensive and painstaking investigation which it displays.

In 1904 Frost published an important paper in which he described as many as seven different technical procedures for the investigation of bacterial antagonism both on solid and in liquid media. One of his most interesting techniques was to interpose a collodion membrane between culture fluid containing the organism he was trying to inhibit and culture fluid containing the organism which he suspected of producing an antibiotic. Fig. 4 is his illustration of this technique.

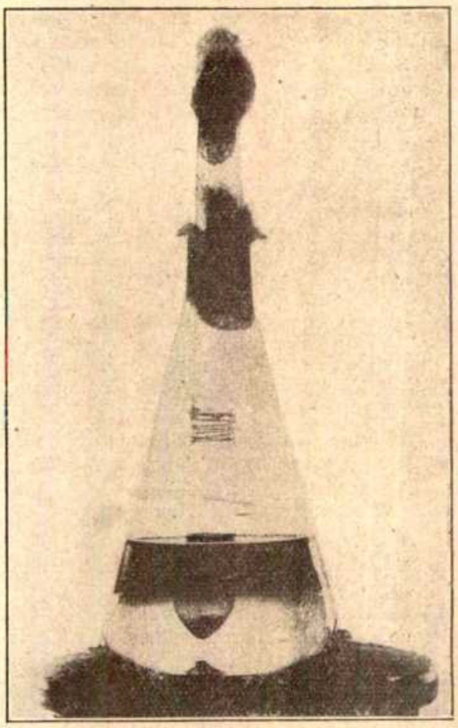

FIG. 4.—Frost's (1904) collodion sac for the study of bacterial antagonism. One organism is sown in the broth in the sac and another in the broth outside it in the flask. Inhibitory substances can pass through the collodion membrane, but the bacteria are kept apart.

The First Crystalline Antibiotic from a Mould

Somewhat before this time the first example of a crystalline antibiotic obtained from a mould was recorded. The mould was a *Penicillium* and the antibiotic is now called mycophenolic acid. Gosio, who did this work in 1896, showed that the crystalline material inhibited the growth of anthrax bacilli, but regretted that he was unable to perform any animal experiments owing to lack of material.

Chemotherapeutic Experiment

Nicolle demonstrated in 1907 the existence of bactericidal substances produced by *B. subtilis*; but of more immediate clinical interest are observations published by Rappin in 1912 in a journal which probably circulates little outside France. He found that *B. subtilis*, *B. mesentericus*, and *B. megatherium* acted strongly on *B. tuberculosis in vitro* and that the effect could be produced by filtered broth cultures. He went on to say:

> "After having established a long time ago that these diastases [as he believed the active substances to be] were very active I naturally went on to consider whether they might not have important effects on the evolution of the tuberculous process. Nearly two years ago I started an investigation with the object of verifying this hypothesis. Several guinea-pigs which had previously been infected with tuberculosis were injected with filtered cultures of *B. mesentericus*, and I possess to this day one of the first series of animals which, treated in that way, lived more than 21 months after a virulent inoculation, with every appearance of perfect health. Another which died after 9 months had put on weight regularly and shown no sign of illness, and no lesion was seen at necropsy except a swelling at the site of inoculation and one in the opposite side. It is a very important fact that scrapings from these swellings inoculated into another animal have not so far

produced in it any sign of a reaction. When this experiment was repeated on other guinea-pigs similar results were obtained, and I have several animals which were treated in this way at varying intervals after infection with tuberculosis which are apparently in good health, while the controls have died with the classical lesions of experimental tuberculosis. These results have been obtained with a relatively small number of injections. Some animals received only two injections of filtered *mesentericus* broth in doses of one to two cubic centimetres given subcutaneously, and others the same amount into the peritoneal cavity. Neither group appeared to be disturbed by the injections, and there were no reactions."

Vaudremer wished to dispute the question of priority with Rappin, for he had found about the same time that *Aspergillus fumigatus* would also "digest" the tubercle bacillus. It is now known that this mould produces four powerful antibiotics, at least one of which—helvolic acid—has been shown to be active *in vitro* against *M. tuberculosis*. In 1913 he reported animal experiments, and went on to say that he had injected *A. fumigatus* filtrates into man, in the following terms (the italics are Vaudremer's):

> "From the point of view of the treatment of tuberculosis in man any conclusion is premature. *Since 1910 we have treated more than 200 patients with extracts of A. fumigatus* in several hospitals and sanatoria in Paris. From the cases we have observed it is justifiable to conclude that the injections, which have never caused any febrile reaction, are harmless. Sometimes healing which we had not hoped for has taken place unexpectedly. In other cases there has been transient improvement, but unfortunately there are still many instances in which the tuberculous process continues to take its course."

He had obviously been trying to get a direct effect on the tubercle bacillus *in vivo* by injecting a mould metabolism solution.

Replacement Therapy

It will be recalled that Cantani had tried in 1885 to replace the tubercle bacillus with *Bact. termo*, and in 1909 this idea received another application. Schiøtz, a Danish physician, noticed that a patient with a staphylococcal infection, wrongly diagnosed as having diphtheria and placed in a diphtheria ward, did not develop the disease. Schiøtz then deliberately sprayed suspensions of staphylococci into the throats of carriers with, he claimed, good results. Many other people tried a similar procedure at different times, and some claimed that benefit was obtained—at any rate, none mentioned any disastrous infection from the staphylococcus. It may sound a somewhat absurd and empirical procedure in the absence of bacteriological information, but it is, as a matter of fact, true that many strains of staphylococcus will inhibit the growth of the diphtheria bacillus —as was shown, for example, by Dujardin-Beaumetz in 1932. In 1915 Colebrook suggested using the pneumococcus in the same way to combat the meningococcus in carriers, following on an *in vitro* observation of antagonism. Later still, in 1921, the pneumobacillus of Friedländer was suggested by Papacostas and Gaté for the treatment of diphtheria carriers.

The best-known example of replacement therapy, however, was furnished by the suggestion of Metchnikoff for the displacement of harmful gut organisms by the Bulgarian bacillus, which was later to give place to *B. acidophilus*. There is a very considerable literature on this subject, into which we will not go except perhaps to call attention to the fact that the lactic acid bacillus was used for the treatment of various infections in addition to those of the intestine. Newman in 1915, in this country, was treating cases of cystitis by injecting lactic acid bacilli into the bladder, and many authors treated infections of the nose, mouth, and sinuses, including diphtheria. Cultures of the bacilli found application in the treatment even of puerperal fever, breast abscesses, and other infections. The good clinical effects were ascribed to the production of lactic acid, which stopped the growth of the pathogens.

Another interesting replacement was suggested by Nissle in 1916. He maintained that certain strains of *Bact. coli* were antagonistic to other and more harmful organisms and that these antagonistic strains should be established in the gut: he even went so far as to say that newborn infants should be deliberately given these desirable strains. He put on the commercial market a preparation of living *Bact. coli* called "mutaflor," which apparently had a considerable sale. Here again there is pictorial evidence that such antagonistic strains of *Bact. coli* exist; for Gratia, who had described such an antagonism in 1925, figured this organism in 1932 (Fig. 5).

In connexion with the idea of "fighting" one intestinal bacterium with another, an interesting line of reasoning was displayed by Nitsch (1908). Apparently at that time two towns in France, Lyons and Versailles, were notorious for their freedom from epidemics of cholera. Nitsch reasoned that the only thing of which all the inhabitants of Versailles partook in common was air, and so it occurred to him that bacteria in the air might inhibit the growth of the cholera organism and if they were swallowed would exert their antagonistic effects in the intestine. On putting this to the proof he found 11 strains of air bacteria out of 220 from various parts of Versailles and 4 out of 253 from Paris which when cultured at 37° C. inhibited the growth of *V. cholerae*. He obviously tested them on solid media, for he described sterile zones round the colonies varying in radius from a few millimetres to a centimetre, while many others had slighter effects. Most of the antagonistic organisms were like streptococci. He thought the next stage was to see if the faeces of the good inhabitants of Versailles harboured these organisms, but apparently this was never done —possibly Nitsch went home to Poland. Another Pole, Choukevitch (1911), carried on the observations with three of Nitsch's Versailles strains—Gram-positive organisms whose colonies had the appearance of streptococci when grown on agar. He confirmed that if a streak of one of these organisms was planted on an agar surface and *V. cholerae* was planted at the same hour on the following day, growth of the vibrios did not take place within a distance of 1 cm. from the antagonist. He found that the inhibition was not due to acid, that the inhibitory substance developed in broth as well as in solid media, and that it was thermolabile and not capable of filtration. He attempted to establish the antagonists in the intestines of newborn rabbits—animals which Metchnikoff had shown to be susceptible to cholera—but he was not able to demonstrate any protection against ingested cholera organisms, perhaps because he could never show that the cocci had established themselves. This episode is of considerable interest in that it was another early attempt to utilize for medical purposes organisms which produced one or more antibiotics.

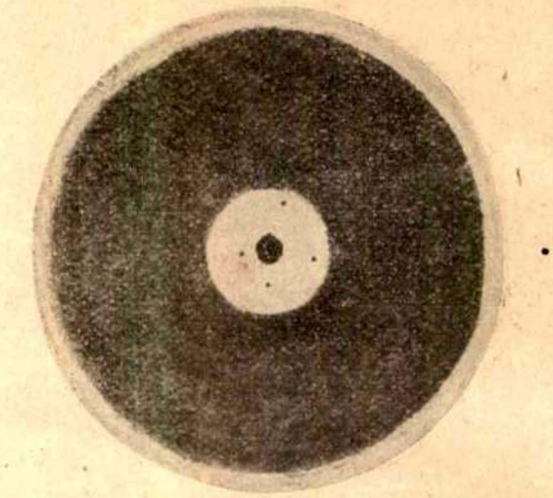

FIG. 5.—Gratia's (1925 and 1932) demonstration of the inhibition of one strain of *Bact. coli* by another. The strain sown over the plate is inhibited round the central colony of the other strain except for a few resistant colonies.

Some New Ideas and Procedures

The nineteen-twenties saw the introduction of some new ideas, new procedures, and new antagonistic organisms. In 1921 Lieske published a monograph on the actinomyces, the great majority of which are harmless soil saprophytes. He wrote: "It is easily shown that actinomycetes secrete a specific substance acting extracellularly. There is a fairly wide zone round an actinomycete colony where other organisms are killed. This inhibition is not simply due to exhaustion of the medium by the actinomycete, for colonies of bacteria which have already grown are lysed and disappear entirely." He studied particularly the effects on killed bacteria, many species of which were lysed, but he also saw lytic and inhibitory effects on live bacteria. He had in mind the possibility of making use of this property in therapeutics in a similar way to that in which pyocyanase had been used but nothing came of this.

Later Gratia and Dath confirmed his observations; they found a streptothrix which was particularly active, and examined many sources for antagonists (Fig. 6). They wrote: "We have exposed plates of 2% gelatin in tap-water, incorporating a suspension of a sensitive microbe, such as the cholera bacillus, to air, and to such vehicles as tap-water, drain-water, mud, etc. By this means we have isolated active colonies not only of the usual streptothrix but of other moulds and also of various saprophytic bacilli, both Gram-positive and Gram-negative. As we see it these are examples of a general phenomenon in which a great variety of agents act against many saprophytic and pathogenic bacteria. Among these agents the streptothrices are the most widespread and the most active." Gratia proposed to use the lytic powers of his streptothrix for the purpose of preparing vaccines. He dissolved certain organisms, such as the staphylococcus, by means of the product of the streptothrix later called actinomycetin, and produced what was known as a mycolysate. This mycolysate was used for immunizing purposes with, it was claimed, results which were better than those obtained by ordinary vaccines. This idea, however, was not even then new, for Nicolle had performed experiments on animals in 1907 in which he showed that immunity could be produced by using the products of *B. subtilis*. Working in 1923, 1924, and 1925 with the same group of spore-forming organisms, Kimmelstiel, Much, and Sartorius had described the production of a lysin from certain *B. mycoides* strains which they named *B. cytolyticus*. By means of this organism lysates of numerous pathogenic organisms were made and produced commercially under the name of "sentocym," and there are clinical reports of their efficacy in such conditions as *Bact. coli* infection of the urinary tract. As well as using it for producing vaccines, Much had the idea of employing the lytic substance as a chemotherapeutic agent, for he wrote:

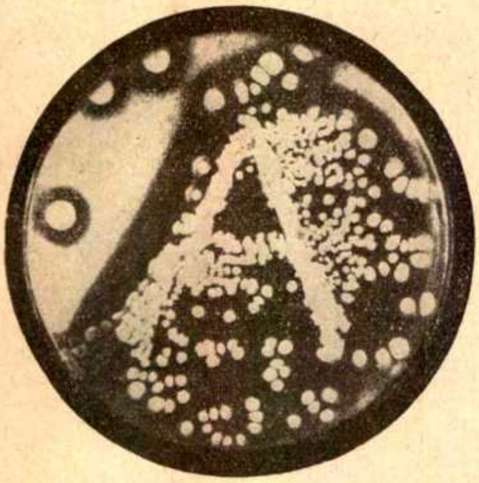

FIG. 6.—Demonstration by Gratia and Dath (1924 and 1934) of the lytic power of a streptothrix. The gelatin contained a heavy emulsion of staphylococci. After 3 days, as shown, there was lysis of the staphylococci round the streptothrix (planted in the shape of an A), and after 7 days the plate had cleared completely.

> "The material for injection obtained by the activity of *B. cytolyticus* contains, firstly, a solution of a particular bacterium, that is a colloidal dispersion of the bacterial content—the lysate. Secondly, it contains the dissolving agent—the lysin. This lysin acts in three ways. Firstly, the bodies of the highly reactive *B. cytolyticus* (Much) form a powerful unspecific therapeutic stimulus. Secondly, the lysin acts on the infecting bacteria in the body as a lytic agent and so frees the body directly from the bacteria. We are dealing here, therefore, with a real 'bacteriolytic' power, which is quite different from the hypothetical power of a serum. This power is clearly and unambiguously shown *in vitro*. Thirdly, products from the bacterial bodies destroyed *in vivo* by the lysin are added to assist the stimulating action of the lysate."

In 1925 Zukerman and Minkewitsch found on a plate of pseudo-diphtheria bacilli an accidental contaminant which was antagonistic to their growth. This is yet another example of an accidental contaminant which was noticed because of its inhibitory properties and subsequently isolated and examined. The organism was *B. mesentericus vulgatus*, and it showed antagonism only to diphtheria and pseudo-diphtheria bacilli, not to staphylococci, *Bact. coli*, *Bact. typhosum*, or a number of dysentery bacilli. Just as pyocyanase and the substance of Lode had selective antibacterial action, so this material showed the phenomenon to a very marked degree. The antibacterial substance was demonstrated to be mainly bactericidal—a 1% solution of a broth filtrate being potent enough to kill *B. diphtheriae* in 24 hours. Experiments were done with animals to see if the filtrate, the activity of which was heat-stable, was capable of affording protection to guinea-pigs against *C. diphtheriae*; but no sure results could be obtained, and the authors did not report them in detail. In 1925 Rosenthal also contributed work on the bacteriolytic powers of *B. scaber*, another spore-forming organism.

In 1929 Fleming noticed an accidental contaminant—a mould this time—which was also lytic to certain pathogenic organisms. The substance it produced was found to appear in the broth and to belong to the slow-acting type of antiseptic. It had marked differential powers of inhibiting bacterial growth. The crude metabolism liquid was shown not to be more toxic to animals than broth in which nothing had grown. No experiments were performed on experimental infection in animals, but the suggestion was made that the substance would be useful for dressing septic wounds in man, and indeed some were so treated without, however, any very striking results. The clinical possibilities of this antibiotic were not pursued at that time.

About that time, too, the explanation was forthcoming of why pyocyanase had largely dropped out of use in the clinic, as Lode complained when he wrote in 1929, referring to the views of Sonnenberger (1913): "In spite of these recommendations papers on therapy with pyocyanase have almost disappeared from recent literature. This is unjustifiable, so experienced clinicians like Herzog the otologist inform us, for the base of suppurating or very dirty wounds is cleaned quickly without damage to the tissues." There is no doubt that active pyocyanase had often been prepared in the laboratory, and probably commercial preparations had been active at first; but Wagner in 1929 and Kramer in 1935 showed that what activity commercial pyocyanase possessed at that time was almost entirely due to its contained phenol—a good example of what may happen to commercial biological preparations without the necessary strict control. How powerful active pyocyanase can be is shown by the recent work of Rake *et al.* (1943), who found that it inhibited the growth of *Str. pyogenes* at a dilution of 1 in 24,000.

In the nineteen-twenties another idea which has never been thoroughly examined was introduced by Schiller (1924a, 1924b, 1925a, 1925b, 1927; Schiller and Giltscher, 1928). In a series of papers he brought forward evidence that yeasts and possibly other organisms could be made to produce substances that were antagonistic to certain bacteria by growing them on media in which the only source of nitrogen was the bodies of the bacteria it was desired to antagonize. He claimed that in such experiments yeasts developed a thermolabile inhibitory substance which might be of value in therapeutics. He called the phenomenon "induced" antagonism, in contradistinction to the "natural" antagonisms we have so far been considering, and it seems likely that much more might be done to develop this line of research.

During the nineteen-thirties examples of antibiotic effects continued to be recorded and some suggestions made for therapeutic employment of the products; for example, Weiland in 1936 described the action of *B. mesentericus* against diphtheria bacilli and proposed that culture material from this organism would be at least as good as pyocyanase.

The Position in 1939

We may perhaps summarize the position at the end of the nineteen-thirties thus. A very large number of observations on antibiosis had been recorded from 1877 onwards—some of the most striking have been considered, but there were a great many more—and from all this work certain proposals had emerged for the use of micro-organisms in therapeutics:

1. The replacement of a pathogenic organism by another and less harmful organism—for example, "*Bact. termo*" to replace the tubercle bacillus in the lungs; staphylococci to replace diphtheria bacilli, and pneumococci to replace meningococci, in the throat; lactic acid bacilli and *Bact. coli* to replace organisms infecting the intestine.
2. Artificial immunization by one organism to protect against infection by another.
3. The use of lytic substances from one organism for the preparation of soluble vaccines of other species—for example, Much's sentocym and Gratia's mycolysates.
4. The use of soluble bacterial or mould products by parenteral injection to treat established diseases—for example, pyocyanase in anthrax, and Vaudremer's extracts of *Aspergillus fumigatus* and Rappin's extracts of *B. subtilis* in tuberculosis. These were examples of true chemotherapeutic use.
5. The use of soluble bacterial or mould products as a topical application for the treatment of local infections—for example, pyocyanase and penicillin broth.

The Crystalline Polypeptides

In spite of an enormous bulk of work extending over 70 years, much of which has not been considered here, up to the end of the nineteen-thirties no antibiotic substance from a mould or bacterium had found an undisputed and permanent place in medicine. But in 1939 important papers were published by Dubos in which he described the isolation of a very active selective antibiotic from a spore-forming soil bacillus, *B. brevis*. The work embodied in these and subsequent papers comprised systematic and detailed investigations, both chemical and biological, and reached a new level in the scientific investigation of antibiotics. The active substance, now called tyrothricin, was separated into two crystalline polypeptides—gramicidin and tyrocidine—the first of which was particularly active against Gram-positive organisms such as pneumococci and streptococci. With this material animal experiments were performed, and it was shown that, although it was very toxic when introduced intravenously, it protected mice infected with pneumococci intraperitoneally to a high degree when small amounts of the drug were introduced into the peritoneal cavity even some hours later than the infecting dose of organisms. The work was then carried to the clinic, and it was clearly established that in some ways this antibiotic was superior to any known chemical antiseptic for local application to sites infected with susceptible organisms. A very considerable literature has now collected on the subject, some of it reminiscent of early pyocyanase work, and it seems probable that gramicidin will not occupy a permanent place in medicine only because of the discovery of less toxic substances soon after its introduction. Such, however, is the repercussion of one branch of science on another that *x*-ray analysis of these crystalline polypeptides and others like them may help to elucidate the structure of proteins. Already much interesting chemical and biochemical work has been done on these substances.

Penicillin

We have seen that the idea of using an antibiotic for parenteral injection into an infected animal had been brought forward for pyocyanase by Emmerich and Löw, for the products of *B. subtilis* by Rappin, for *B. mycoides* by Much, and for *Aspergillus fumigatus* by Vaudremer, but no antibiotic had been unequivocally shown to possess curative properties when so used. In 1940 the first observations on penicillin from Oxford were published (Chain *et al.*) which distinguished clearly this antibiotic from any of the preceding ones, for up to this time the real significance of penicillin had escaped detection. There are a large number of substances of both synthetic and natural origin which kill bacteria. Unfortunately most of them also damage animal tissues. Lister clearly realized this in the early days of antiseptic surgery. As his biographer, Godlee (1917), wrote:

> "The antiseptic system aimed at destroying the germs by chemical agency, either before they gained access to a wound at the time of its infliction, or so soon afterwards that they had no chance of developing and multiplying; and, this end having been attained, it further aimed at preventing by means of chemical antiseptics the access of germs to the wound until the process of healing was complete. The problem as thus stated sounds simple, and so it appeared to be in the early days. But, even from the first, one great complication was apparent. Lister recognized the power of the living tissues to control the growth of micro-organisms, and the importance of not interfering with the vitality of the tissues by any harmful agency whatever. Therefore he felt bound to reduce the strength of the chemical substances which he employed to the minimum consistent with efficiency."

It has been seen how pyocyanase was used as a local antiseptic, and later it was proposed that penicillin broth could be used in the same way. The experimental work at Oxford disclosed, however, that an extract containing penicillin could be made which was of such incredibly low toxicity that it could be injected intravenously or by other parenteral routes in amounts far greater than those required for therapeutic effect without producing any sign of toxicity (Abraham *et al.*, 1941). It could thus circulate in the blood and body fluids in sufficient quantity to destroy sensitive bacteria in combination with the natural body defences without the least damage to those defences or to other tissues.

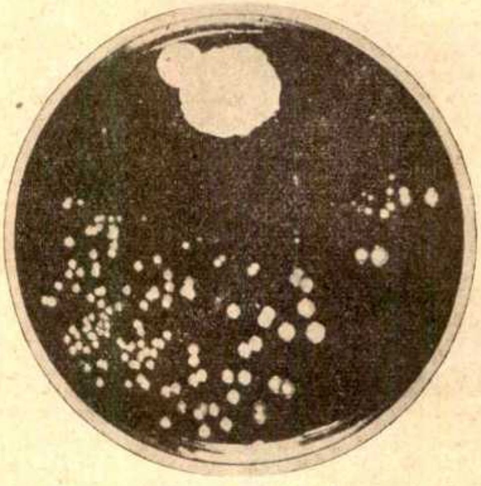

FIG. 7.—Photograph of a culture-plate showing the dissolution of staphylococcal colonies in the neighbourhood of a penicillium colony. (Alexander Fleming, *Brit. J. exp. Path.*, 1929, **10**, 226.) (Reproduced by permission of the Editors of the *British Journal of Experimental Pathology*.)

This clear-cut experimental demonstration of its chemotherapeutic action was the starting-point of the serious endeavour to apply penicillin in the clinic. By the time these observations were made—in 1940 and 1941—it had already been clearly established that synthetic chemicals of the sulphonamide group could be absorbed into the blood stream in sufficient concentration to deal in a spectacular manner with many infections—for example, lobar pneumonia and meningococcal meningitis and certain streptococcal infections such as puerperal sepsis. It was natural to suppose that these compounds would be of the greatest use in war surgery, and they were employed in large amounts both by mouth and by local application to wounds throughout the war. Probably the sulphonamides have been instrumental in diminishing generalized sepsis by preventing the spread of streptococci from wounds into the blood stream, but it was evident fairly early in the war that their use was not the final solution of the treatment of the suppurating wound or even for prophylaxis. The main reason for this is probably that there exist many inhibitors of the antibacterial action of the sulphonamides and that some of these are present in pus and in the breakdown products of tissues. It was therefore of the greatest good fortune that it had been discovered by 1941 that extracted penicillin was fully active in the presence of pus and tissue breakdown products, for it was the knowledge of this fact in conjunction with knowledge of the diffusibility and lack of toxicity of the extracts which made much of the subsequent work to bring the substance into clinical use appear worth the great effort necessary. From the results of experimental work it seemed more than likely that penicillin could be applied with success to septic infections involving pus formation either by injecting it into the blood stream or by local administration. These expectations have been fully borne out by subsequent clinical investigations, which have shown clearly that infection by sensitive organisms can be checked and overcome. An additional encouragement lay in the fact that the staphylococcus was highly sensitive to penicillin, thus bringing into its therapeutic field a group of infections which were outside the range of any of the sulphonamides then known.

In the use of penicillin in war surgery there has been an evolution. Attention was at first directed to the relatively small proportion of wounds which had become severely and chronically infected, as it was thought that here the small amounts of penicillin then available would have the greatest effect. But the slow and sometimes disappointing progress in these deeply infected wounds drew attention to the fact that the use of penicillin in warfare involved not one consideration but two—not only the best methods of application but also the best time at which to make the application. So a move was made to the forward hospitals, and wounds of a few days' standing, even though septic, were treated by appropriate surgery, including suture, and penicillin applications, and in this way an attempt was made to prevent serious and chronic sepsis ever developing. Later, when penicillin became more plentiful —at the time of the invasion of North-West Europe—it was possible to give penicillin prophylactically soon after wounding. Though many factors have contributed to the excellence of the surgical results obtained in the later years of the war few will, I think, now dispute that penicillin has played an important part.

You would not wish me to describe again the reasoning on which the procedures for the use of penicillin in surgery were founded, but on this occasion it may be appropriate to point out that the position has now been reached when a very great measure of success can be claimed in the treatment and prophylaxis of sepsis for a combination of aseptic methods—that is, of methods not associated with chemicals and of antiseptic methods which involve their use. The really important point with regard to the latter is the recognition that there exists an antiseptic beyond the dreams of Lister—an antiseptic which can be applied through the blood stream as well as by appropriate local means, one immensely powerful against many pathogenic organisms but at the same time harmless even to very delicate tissues, and one fully active in surroundings where the sulphonamides fail.

An Outburst of Research

With the demonstration that at least one of the antibiotics was not simply an antiseptic, as had previously been supposed, but a chemotherapeutic agent in the sense in which that word is now used, a great outburst of research has taken place all over the world. Workers who had abandoned the field years ago again became interested, and it was not long before the air was filled with the cries of those wishing to join the new experimental gold rush and to secure what had previously been abandoned. In these days it is uncommon to peruse a medical journal without finding a record of some new organism with antibiotic powers or the re-examination of one already known. One of the most piquant has recently appeared: a mould isolated from human hair in New York has been found to produce a red dye which is active against *Bact. coli.* What a chance for journalists, who have already shown something of their imaginative powers in connexion with penicillin, to wax lyrical and romantic if this substance should ever be of therapeutic importance and it should be disclosed that it was a woman's hair ! I cannot help feeling that Lister would be mightily amused to see the army of eager enthusiasts now stretching out suppliant Petri dishes in the hope that they will receive some miraculous therapeutic manna. Some workers think that the energy spent in the search for new antibiotics would be more profitably spent in investigating more minutely the action of those already known, with the object of understanding bacterial metabolism better. This may be true, but, on the other hand, the search for more antibiotics with a chemotherapeutic action may be of service to surgery; for, successful as the application of penicillin has been not only in war but also in civilian surgery, it cannot be said that all forms of sepsis can yet be controlled. Penicillin is ineffective against the Gram-negative bacilli, such as *Ps. pyocyanea*, *Bact. coli*, and *Proteus*, and these organisms can still cause mild suppuration in wounds free from streptococci and staphylococci. There is in addition the possibility of resistant strains arising, and though this has so far happened relatively rarely with penicillin, alternative drugs which will do for penicillin-resistant strains what the latter has done for some sulphonamide-resistant strains would be a valuable acquisition. The search, perhaps less urgent now the war has ended, goes on, and already a most interesting compound, streptomycin, has been isolated by Waksman and his collaborators (Schatz, Bugie, and Waksman, 1944) from an actinomycete—one of the group of organisms which, it will be recalled, was first shown to produce antibiotics by Lieske in 1921. Streptomycin is a base which is remarkably non-toxic to animals and can be given in large doses in much the same way as penicillin, and it is active against some of the Gram-negative organisms such as *Bact. coli* and *Ps. pyocyanea.* It has been shown, in mice, to have true chemotherapeutic action against infection by *Ps. pyocyanea* and other Gram-negative organisms, and it has been tried clinically—though with no clear-cut success—in typhoid fever and other infections. It has also some effect, both *in vitro* and experimentally *in vivo*, against the tubercle bacillus. As yet little has been reported of its use in surgery. Besides this most interesting compound this group has furnished streptothricin (Waksman and Woodruff, 1942), similar to but more toxic than streptomycin, and proactinomycin, a substance isolated by Gardner and Chain (1942) from an accidental contaminant. This last substance acts against Gram-positive organisms, and has recently been shown to have chemotherapeutic properties against peritoneal infection by the streptococcus when given by mouth (Florey, Jennings, and Sanders, 1945). It may be a measure of the progress in the chemotherapeutic field that this fact has not excited us greatly, for eleven years ago, before the discovery of the sulphonamides, it would have been considered almost miraculous. Some recent unpublished work which the authors permit me to mention illustrates clearly how very careful one has to be in assessing the powers of antibacterial substances. These three substances from the actinomycetes are all bases, and Dr. Abraham and Dr. Duthie find that their antibacterial power is considerably altered by relatively small changes in the reaction of the medium in which they act. Thus at *p*H 8 their activity is many times greater than at *p*H 7, and at *p*H 7 more than at *p*H 6. When it is realized that autolysing tissues and pus are quite acid it becomes clear that *in vitro* observations carried out in media at *p*H 7.4 or thereabouts may give far too optimistic a picture of what these substances are capable of achieving in the body.

Another development which illustrates fully the great importance of the biochemist in this field of work has recently been furnished by Doisy and his colleagues (1945). Biochemists and bacteriologists working together have isolated four crystalline substances from the organism on which so much sustained work was done in the early days—*Ps. pyocyanea.* These substances, which the workers call Pyo I, II, III, and IV, act powerfully against Gram-positive organisms and appear to have little toxicity to animal tissues, but experiments with infected animals have not yet been reported. It would be intensely interesting if this organism which has been worked on for so long should at last yield a substance of permanent value in therapeutics.

The field for research is obviously vast, and at the moment much attention is being applied to the possibility of discovering an antibiotic which will be effective against tuberculosis. That such a possibility exists no one will deny, but the urge to fame is such that I greatly fear there will be many unreliable and premature publications on this subject. The exploration of the possibility that skin fungal infections and protozoa may be susceptible to some antibiotics has only just begun—with what prospects no one can yet say.

Conclusion

I hope I have been able to make clear that the present happy position in the prevention and treatment of sepsis has not been reached by a flash of insight on anyone's part, but that we at Oxford made a choice from among the many antibiotics known and had the great good fortune to be able to show for the first time that an antibiotic could also be a chemotherapeutic agent.

One great lesson which a survey of work on antibiotics should have taught us is that real and continuous progress and understanding can be obtained only by the collaboration of people with various outlooks and experimental accomplishments, and, in particular, that little progress can be made without first-class biochemical work. The other important point is that steady and rapid progress is possible in the clinic only when the clinician has firmly based experimental foundations on which to work. It is easy to exaggerate the importance of antiseptic drugs in surgery, and I have indeed noticed signs of restiveness among surgeons when misguided people have wished to attribute all their success in dealing with septic conditions to penicillin. I have always maintained that the introduction of such drugs demands better, not worse, surgery, and a better understanding of inflammatory processes. And it is, I think, quite clear that penicillin and substances like it will only be used with maximum effect if surgeons have a real appreciation of the properties of the drugs—not only what they can do, but also what they cannot do and the reasons for their limitations.

Perhaps I may close with some words of Lister's written in 1867: "And I may take this opportunity of warning some of your readers that they must not expect carbolic acid to act like a charm; but that, whether they employ this agent or some other of analogous properties, it is only by the light of sound pathology, and strict attention to practical details, that they can hope to attain in their full measure the magnificent results which the antiseptic treatment is capable of affording."

NEUROLOGICAL COMPLICATIONS OF INFECTIVE HEPATITIS

BY

J. F. STOKES, M.B., B.Chir.
Lieut.-Col., R.A.M.C.

J. R. OWEN, M.R.C.P.
Lieut.-Col., R.A.M.C.

AND

E. G. HOLMES, M.D.
Lieut.-Col., R.A.M.C.

Cerebral changes in fatal cases of infective hepatitis have often been recorded. They have usually taken the form of coma, delirium, convulsions, and incontinence—symptoms which are common to the clinical picture of acute hepatic necrosis of any origin. Other neurological findings are, however, less well recognized, and it is the purpose of this paper to discuss various signs observed independently in cases of infective hepatitis by four persons in different parts of Assam and Bengal during 1944.

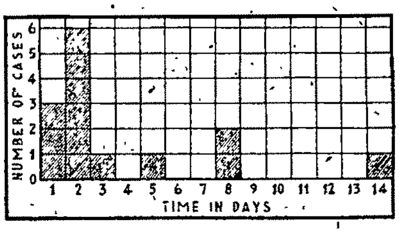
The neurological findings have been protean, but it is possible to dissect out four main groups. First, the picture commonly found in the fatal case, which is too familiar to need detailed description. Secondly, a symptom-complex comprising generalized or localized muscular rigidity with increased tendon-jerks, sometimes but not invariably associated with extensor plantar responses; in addition chloreiform movements have been observed, and in one case a Parkinsonian tremor. Thirdly, a group of cases with large focal haemorrhages into nervous tissue, which may or may not produce localizing signs. Fourthly, those cases showing signs of peripheral neuritis for whose direct relation to the onset of infective hepatitis there is good evidence.

The Common Type

This group may be illustrated by a "type" case:

S., aged 28, developed anorexia, followed by jaundice and bile-stained urine, on Dec. 19, 1944. He remained deeply jaundiced, and on Jan. 3, 1945, became drowsy and apathetic. The liver dullness was diminished, but there were no objective signs in the nervous system. On Jan. 4 he became alternately stuporous and maniacal. The urine contained no leucine or tyrosine crystals, and the cerebrospinal fluid, under a pressure of 100 mm., contained 60 mg. of protein per 100 c.cm. He died on Jan. 5. Necropsy showed characteristic changes of acute hepatic necrosis in a liver that weighed 750 g. The only demonstrable change in the brain was that of congestion of small vessels in the white matter.

There is nothing unusual about this case, but it illustrates well the short time that often elapses between the first onset of mental change and death. A histogram of this interval in 14 cases is shown in the accompanying figure.



Interval between onset of mental changes and death in 14 fatal cases of infective hepatitis

Some degree of mental depression is very common in infective hepatitis. Any increase in this depression or any behaviour change should be treated as a danger sign and as an indication for such protective therapy as is available.

The Striatal and Pyramidal Group

Nine cases have been observed in this group. The distribution of the relevant physical signs is shown in the accompanying Table. The following are brief histories of Cases 4 and 6.

Case 4.—A British private aged 30 was admitted on May 25, 1944, complaining of anorexia and dark urine for two weeks and jaundice for 10 days. On examination he was afebrile and deeply jaundiced.

The liver was palpable and tender. Otherwise there were no abnormal signs. There was bile in the urine, and a diagnosis of infective hepatitis was made. There was normal progress up to May 31, when the jaundice was barely discernible, except that he had been found sleep-walking on the nights of May 29 and 30. He was not, so far as he knew, in the habit of sleep-walking. On May 31 he was drowsy all day, but took food and answered when spoken to. In the evening he became distant and unapproachable, and the same night was incontinent of urine. Examination revealed slight spasticity of both arms. On June 1 he was in coma. There was deep jaundice and the liver was still palpable. Both arms were spastic, adducted, and pronated. Both legs were spastic, adducted, and extended. Plantar responses were flexor. All tendon-jerks were very brisk and there was sustained left ankle clonus. The pupils were not dilated and gave normal reactions; corneal reflexes were absent; fundi were normal. During the day these physical signs remained unchanged, but there appeared in addition choreiform movements of both arms, more marked on the right side, and purpuric spots on both upper arms. He died early on June 2 with more purpura on the right hand and a sharp terminal rise of temperature. Lumbar puncture revealed no abnormality. A white blood count showed a slight polymorph leucocytosis. There were no malaria parasites in repeated blood slides. There was no albuminuria.

Distribution of Striatal and Pyramidal Signs in 9 Cases of Infective Hepatitis

Case No.	Muscular Rigidity	Increased Jerks and Clonus	Involuntary Movements	Extensor Plantar Responses	Outcome
1	+	—	—	—	Death
2	—	+	—	—	"
3	—	+	+*	—	"
4	+	+	+*	—	"
5	+	+	+†	—	"
6*	+	+	—	+	"
7	—	+	—	—	Recovery
8	+	+	—	+	"
9	+	+	—	—	Death

* Frank choreiform movements. † Parkinsonian tremor of hands.

At necropsy there were numerous subpleural, subpericardial, and mesenteric petechial haemorrhages. The liver was not diminished in size; it had a red-and-yellow blotchy appearance and the architecture was clearly destroyed in patches. The brain showed no macroscopic abnormality, there were no malaria parasites in brain smears, and there was no bile staining of brain tissue.

Histology.—Liver:—Marked degeneration of the parenchyma with a moderate amount of fibrosis and cellular reaction. Proliferation of bile ducts and formation of new parenchyma very pronounced. Evidence of degeneration even in newly formed epithelial cells. Brain:—Generalized oedema of white matter. No perivascular cuffing or general increase in cells. No cellular degeneration. Virchow–Robin spaces widely separated from the vessels. A small extravasation of red cells into the brain tissue from one vessel in the midbrain.

Case 6.—A British N.C.O. aged 24 was admitted on Sept. 16, 1944, complaining of anorexia for five days and dark urine for three days. On examination he was moderately jaundiced and there was bile in the urine. There were no other abnormal signs. Infective hepatitis was diagnosed. On Sept. 19 he became drowsy yet restless. Jaundice was more intense and the liver dullness was diminished. There were no abnormal signs in the nervous system. Later in the day he became delirious. On Sept. 20 he was still more deeply jaundiced and in coma. The pupils were dilated but not fixed, and the fundi were normal. There were bilateral extensor plantar responses, but no alteration in muscular tone and no involuntary movements. Later in the day his temperature rose slightly. Both legs became spastic and were held adducted and extended. There was bilateral sustained ankle clonus. The temperature rose steadily to 105° during Sept. 21, coma deepened, and the physical signs remained unchanged. He died early on Sept. 22. There was never any purpura. The urine contained no albumin, and repeated blood smears were negative for malaria.

Necropsy revealed endocardial petechial haemorrhages. The liver was small and flabby with a shrunken capsule, and the cut surface was blotchy yellow and red. The brain showed no macroscopic abnormality, no bile staining, and negative smears for malaria parasites.

Histology.—Liver:—Extensive parenchymatous degeneration with marked leucocytic infiltration. Brain:—Generalized oedema, especially of the white matter. Perivascular lymph spaces greatly enlarged. No haemorrhages. No degenerative changes. Occasional vessels in the caudate and lentiform nuclei showed a few round cells, perivascular, but the appearances were not suggestive of an encephalitis.

In all fatal cases the liver showed the characteristic pathological changes of acute or subacute hepatic necrosis. Histological sections of the brain are available in five cases, including the two detailed above. They consisted of scanty round cells, perivascular around the basal ganglia, in the meninges, and in one case in the subcortical white matter. A greater or lesser degree of cerebral oedema was always present, and extravasation of small numbers of red blood cells throughout the brain was sometimes observed. These changes are in alignment with those found by Baldwin Lucké (1944) in his excellent analysis of fatal hepatitis in the U.S.A., except that in one of our cases lymphocytic infiltration was found in the subcortical white matter as well as in the meninges and basal ganglia.

The pyramidal and striatal signs may be accounted for by one of three theories: a mutation of the infective hepatitis virus, giving it a neurotropic character; a specific attack upon the basal ganglia and pyramidal systems by products of autolysed liver cells; or by toxins from the gut which are allowed to pass through an incompetent liver.

The virus theory is improbable on account of the following facts. The onset of striatal signs coincides with a sudden increase in liver damage and not with the onset of the infection. The cellular reaction round the small vessels of the brain is very slight and can hardly be considered to indicate a meningo-encephalitis. It is conceded, however, that the tempo of the disease, once cerebral changes have appeared, is so swift that more dramatic histological changes may have no time to appear; again, it is possible that special methods of staining which were not available might have demonstrated more extensive damage.

The chemical theory is more likely. It is interesting to note the relation between striatal and pyramidal disease and diffuse liver damage in such diverse conditions as kernicterus (Hawksley and Lightwood, 1934), umbilical infection (Biemond and van Crefeld, 1937), Kinnier Wilson's disease (Greenfield, Poynton, and Walshe, 1924), Laennec's cirrhosis (Waggoner and Malamud, 1941), and such metabolic disturbances as haemochromatosis and the lipoidoses (Brouwer, 1936). Many of these conditions are characterized by diffuse liver disease of a chronic nature in which there is no active autolysis of liver cells. It is for this reason that we prefer the last explanation—namely, that of poisoning of nervous tissue by the passage of intestinal toxins through an inefficient liver.

The pathogenesis of these signs is probably the same as that of the "type" picture, but the association between hepatic and striatal damage in so many diseases is too frequent to be pure coincidence and demands further investigation.

The Haemorrhagic Group

It is the rule rather than the exception to find diffuse petechial haemorrhagic phenomena in fatal cases of infective hepatitis as in any disease causing liver failure. We have observed three cases which are worth noting, since they showed massive haemorrhages—into the caudate nucleus in one case, and forming a subdural haematoma in the other two.

Case A.—A British officer became ill on July 1, 1944, with nausea and vomiting followed by jaundice. On July 14 he became unconscious and incontinent; the plantar responses were both extensor, but later in the day the right response became flexor. On July 18 there was a petechial rash and he bled extensively from ulcers on his scalp, shoulder, and wrist. Necropsy on July 22 showed the common hepatic changes of necrosis; the brain contained an area of softening lateral to the right lateral ventricle and a large haemorrhage into the right caudate nucleus. Histology demonstrated small extravasations of blood into the meninges and into the Virchow-Robin spaces in the pons; there was also slight perivascular round-cell infiltration.

Case B.—A sapper developed infective hepatitis on July 26, 1944. There were small subconjunctival haemorrhages and haematemesis. Blood slides showed a few benign tertian rings. On Aug. 3 he suddenly lapsed into coma and died the same day. Necropsy showed a right parietal subdural haematoma. The surface vessels of the brain were congested and there were petechial haemorrhages throughout the white matter. Brain and spleen smears showed no malaria parasites, and the liver changes were those of acute hepatic necrosis.

It is suggested that in the first case the lesion (possibly a venous thrombosis) giving rise to the area of softening occurred at the same time as the extensor plantar response was observed. The caudate haemorrhage which gave no signs was probably terminal. The subdural haematoma both in the case quoted and in the other was silent.

This is a small and somewhat artificial group which should be regarded aetiologically as a gross manifestation of the general haemorrhagic tendency in liver failure.

Peripheral Neuritis

In the Arakan in 1944 there was a small and short-lived outbreak of peripheral neuritis which coincided precisely in time with the development of jaundice in each case. This outbreak will be reported elsewhere by Byrne, who considers, with some reason, that the symptoms and signs of peripheral neuritis were due to the emergence of a neurotropic element in the virus of infective hepatitis. We have observed one such case:

A British private aged 38 complained of a painful heel on July 26, 1944. He had cellulitis of the heel, which cleared up by Sept. 20. There was no open ulcer. He then noticed difficulty in walking (the difficulty involved both legs), and a week later he developed infective hepatitis. Jaundice was persistent, the weakness of the legs became gradually worse, and the arms became weak also. On Nov. 12 (the last day on which he was seen, as he developed amoebic dysentery and had to be evacuated) examination showed normally reacting pupils, no cranial nerve lesion, general weakness of the upper limbs with absent tendon reflexes, and general weakness of the legs with absent knee- and ankle-jerks. There was wasting of the dorsiflexors, with blunted touch sensation on the legs and slight Rombergism.

It seems doubtful whether the peripheral neuritis in this case was causally related to the infective hepatitis. Hurst (1943) observed similar cases in Gallipoli in the 1914–18 war, and it is by no means certain that they did not represent the simultaneous occurrence of two fairly common diseases.

Summary

The neurological complications of infective hepatitis are reviewed.

Four main groups are illustrated by cases observed in Assam and Bengal in 1944.

It is concluded that neurological changes may appear in association with infective hepatitis due to a number of causes, most of which are still a matter for speculation.

Our thanks are due to Lieut.-Col. G. A. Ransome, I.A.M.C., for records of Cases 1, 2, and 3, analysed in the Table.

A TRICK TEST TO DETECT NIGHT-BLINDNESS "MALINGERERS"

BY

E. EPSTEIN, M.B., B.Ch., D.O.M.S.
Major, R.A.M.C.

AND

S. A. HUGH LESSER, M.A., M.B., B.Ch.
Capt., R.A.M.C.

The tests that have so far been evolved to examine scotopic vision—pentagon, hexagon, and the various adaptometers—are all subjective in nature and therefore demand the full co-operation of the subject. From the military point of view this is of little value in eliminating the few genuine cases of night-blindness from the many who simulate the condition. To help in sifting these cases the following test was devised and preliminary experiments have been carried out.

It was thought that if it could be shown that the subject was co-operating fully, then more reliance could be placed upon the subjective results of one of the above-mentioned night-vision tests. A mass of experimental data (Hecht and Williams, 1922; Hecht and Mandlebaum, 1939; McDonald, 1940; Mandlebaum, 1941) indicates that red light stimulates the cones of the retina only and that the rods are unaffected. On this basis, subjects with normal central vision—that is, adequately functioning cones at the macula—should be able to identify a pure red light at minimal intensity even if the rest of the retina is diseased or defective.

Experiments performed by us have shown that the minimum threshold for pure red falls within a very narrow range of intensity of illumination (Fig. 1). An individual with defective night vision but with normal cones—that is, normal macular function—should theoretically be able to see red light within this narrow normal range of minimal intensity. This hypothesis has been confirmed by the few cases of early retinitis pigmentosa, diffuse choroido-retinitis (maculae unaffected), and advanced glaucoma with very contracted fields but good central vision which we have so far been able to test. One possible exception, suggested by the literature (Wald, Jeghers, and Arminio, 1938; Wald and Steven, 1939; Hecht and Mandlebaum, 1939; Mandlebaum, 1941)—for we have not been able to find such a case—is severe nutritional deficiency (vitamin A), because it is reported that in experimentally induced vitamin A deficiency the cone threshold for white light, and therefore we presume the red threshold as well, is raised. In practice, however, this exception can be dismissed, as this condition cannot arise on Army diets and would, in addition, show other well-marked features. Finally, it is necessary that known cases of night-blindness (familial) with no signs of disease or abnormality of the fundi should be tested to ascertain if such cases fall within the above established normal range of minimal thresholds. This would substantiate the universal application of the test.

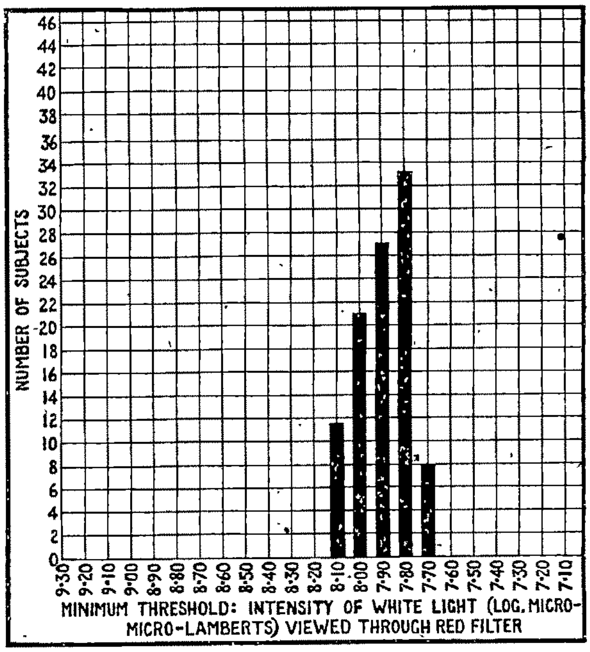

FIG. 1.—Range of minimum threshold for red light of 100 subjects chosen at random and including those with hypermetropic and myopic errors of refraction.

Method

The test evolved is briefly as follows. The individual who complains of night-blindness at the out-patient clinic is given a careful routine examination including colour vision, then placed in a dark room, given dark goggles, and left to dark-adapt for 20 minutes. Other patients are seen meanwhile, so that no time is wasted. After 20 minutes' adaptation the "night-blind" patient is asked to state when he can just see the faint red light which is shown him and increased gradually in intensity; as soon as he can see the light it is dimmed and the test repeated a few times until a constant result is obtained. It is simple to deduce whether the patient is co-operating or not. The general procedure of the test suggests to the subject that his night visual ability is being tested, and the malingerer reasons that he must not admit seeing the light until it is very bright; but this, of course, does not tally with the results of the general routine investigation, which shows that he has normal macular function. Further, the several readings taken often give inconstant results in this type of case, as it is difficult for the malingerer to judge an equal brightness intensity each time.

This test takes up about five minutes of the operator's time. When a result within the normal range is obtained it can be assumed that the patient is co-operating, and one of the tests of scotopic vision can be performed with reliance upon the results.

The apparatus used is Crookes's adaptometer 1944 (Fig. 2) (Godding, 1945), which consists of a screen illuminated by a constant source. The intensity exhibited is varied by neutral density filters and rotating polaroids placed between the screen and the observer. This has been calibrated by the National Physical Laboratory. The red filter used is Dufay-Chromex No. 2257, which transmits the longer waves of red light as shown in Fig. 3—i.e., 680 to 720 mμ. Of the various filters tried this was found to be the best, as it "crossed the threshold coloured," the other filters allowing the transmission of shorter waves, which were perceptible as a faint grey before the light was seen as red, thus making it difficult to determine the threshold and giving a wider variation in the normal range. A square aperture, subtending an angle of 1°, diagonally, at the testing distance, is used in front of the filter, and the patient is placed in position and shown this before the test so that he knows where to look and can fix on it. A square aperture is used as suggested by Sloan (1939) to avoid confusion with the vague sensations of light experienced by subjects at threshold values. A 1° aperture at threshold values for red light stimulates only the macula and is not appreciated by paramacular regions.

FIG. 2.—Horizontal section of Crookes's adaptometer 1944.

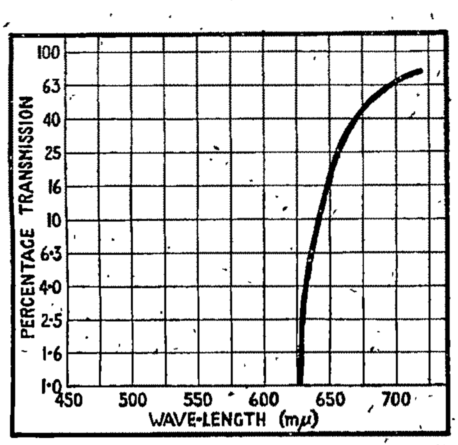

FIG. 3.—Transmission of Dufay-Chromex filter No. 2257.

The subject is first tested without spectacles. It was noted that many cases with high refractive errors gave subnormal results without their glasses and normal readings with them. The value of spectacles in these instances was not only refractive but helped maintenance of fixation, for the esophoria of hypermetropes and exophoria of myopes became manifest in the dark. The more observant of these subjects volunteered that their eyes seemed to have wandered in the dark and that they suddenly saw the red light when they moved their eyes a little to one side. Cases with small refractive errors—less than +3 or −3D—usually gave the same result with or without glasses; or those cases giving a very good result without glasses might give a slightly worse reading, though well within normal, with the spectacles. No doubt the explanation of this is the absorption and reflection by the lenses of some of the incident light.

Illustrative Case Histories

Case 1.—Lieut. A. had complained of night-blindness in 1943, when he was examined at an ophthalmic centre and a very poor result (1/5) was obtained with the Army pentagon test. He was considered bad enough to be excused night duties, but was left in Category A. He was seen in Jan., 1945, after posting to a new unit, the authorities of which considered it incongruous for an officer to be Category A though deemed so night-blind as to be excused night duties. Routine examination revealed no abnormality, but, tested with the red light, he admitted seeing it only when it was very bright and well outside the normal range. Before taxing him with this incongruity he was referred to a psychiatrist—Major McCarthy, R.A.M.C.—who diagnosed an extremely abnormal state bordering on psychopathy.

Case 2.—Lieut. B. had always had difficulty in the black-out. When with the B.L.A. he found that one relatively dark night he was unable to see to drive, and had to employ a driver, who managed quite easily. The fundi showed numerous small retinal cysts (Blessig) which reached to well behind the equator. The red test gave a normal result. The dark-adaptation curve showed a slow rate of adaptation and a final threshold definitely higher than normal. This officer was considered to be handicapped in the dark; he was suitably categorized.

Case 3.—Gnr. C. had difficulty in getting about at all in the black-out. Routine examination, red test, and dark-adaptation curve were all normal. Further questioning revealed the story of an accident during the first month of the black-out, when he had run into the back of a stationary lorry with no tail light and had severely bumped his right eyebrow. He then realized that the pain which he had been experiencing above his eyes in the black-out was a "memory" of this accident. Reassured of his perfect sight, he went away feeling much happier. His medical officer was advised to refer him to a psychiatrist if his symptoms recurred. A follow-up four months later elicited that he had not complained about his eyes and was performing his duties satisfactorily.

Case 4.—Pte. D. had difficulty in driving in the black-out. Red test and dark-adaptation were normal. Close questioning revealed that he disliked driving at any time. He was referred to the psychiatrist, who reported a severe anxiety neurosis necessitating institutional treatment.

Case 5.—Sign. E.'s eyes were normal. The red test showed non-cooperation. Further questioning revealed nothing of note. His medical officer was notified to disregard all complaints of visual defect at night.

We wish to thank Brig. Sir Stewart Duke-Elder for permission to publish this paper, and we are grateful to the Crookes Laboratories for the loan of their adaptometer.

GENERAL ANAESTHESIA AND THE TEMPERATURE OF INHALED GASES

BY

ARTHUR MILLS, M.D.

Late Lecturer in Anaesthetics, University of St. Andrews

AND

MARGARET SOUTAR, M.B., Ch.B.

Hon. Anaesthetist, Dundee Royal Infirmary

It would appear that for long there have been misconceptions regarding the temperature of gases and vapours as presented to the patient for inhalation. There have also been differences of opinion on the advisability of warming these gases. The idea seems particularly to have prevailed that ether vapour must necessarily have the objectionable quality of coldness. Gwathmey (Hewitt, 1912), in 1908, stressed the need for raising the temperature of the vapour in order to prevent the loss of heat by the patient incurred in warming up a cold vapour in his air passages. Seeling (Hewitt, 1912), on the other hand, in 1911, concluded that the warming of anaesthetic vapours was unnecessary. In 1918 Pembrey and Shipway advocated warming the vapour, with a view to maintaining the patient's body heat; Shipway's warmed-ether apparatus was introduced at that time. Minnitt and Gillies (1944b) do not consider that warming the gases is essential when administered by modern methods, but "if, however, the old method of insufflation is used, in which there is no reflux of exhaled gases, and especially if the gases are blown through ether at a fairly high flow-rate—say 8 litres per minute—then the resultant mixture passing into the lungs is of a sufficiently low temperature to be detrimental, and some form of heating is advantageous." Minnitt and Gillies (1944c) state: "There can be little doubt that the blowing of a cold mixture of gas, oxygen, and ether at a high rate of flow—10 litres or more per minute—into the patient's lungs is a major cause of the high incidence of post-anaesthetic respiratory complications, which are frequently noted when continuous-flow machines of the Boyle type are used, or, perhaps one should say, abused."

The closed circuit and the Oxford inhaler are both commended by some because they maintain a *warm* anaesthetic mixture for inhalation. Open ether, when ether is administered by a perhalation system, is almost invariably associated with the appearance of patches of snow on the gauze, and doubtless this suggests to many the inhalation of a "frosty anaesthetic vapour." Referring again to Minnitt and Gillies (1944a), when the subject of shock and anaesthesia is under discussion a factor contributing to shock production is given—namely, "heat loss by exhalation, and particularly if the patient has to breathe through ether on an open mask."

To test the various opinions expressed on this subject the following observations were made. Temperatures are expressed in degrees Fahrenheit, and were taken with a sensitive chemical thermometer. When obviously unimportant, fractions of a degree were not recorded.

The ether in a drop-bottle, the ether, and the ether vapour and air mixture in the ether bottle of a Boyle machine were all at theatre temperature—73°. The face-piece was removed from the 30-in. wide-bore delivery tube of the machine, and the thermometer was inserted well within the face-piece end of the tube. When a mixture of 1 litre of oxygen and 5 litres of nitrous oxide was allowed to flow the temperature was 73°. The mixture was allowed to pass over the ether in the ether bottle—temperature 73°, and then to bubble through the ether in the ether bottle—temperature 73°. Two litres of oxygen and 10 litres of nitrous oxide were now allowed to bubble through the ether; in 10 minutes the outer surface of the bottle was coated with ice; the temperature of the mixture gradually fell to 69°, at which it remained stationary.

Temperatures of the mixtures as actually inhaled by the patient during anaesthesia were recorded in a large number of cases. *Open ether:*—The mask was a simple one covered with 16 layers of surgical gauze. The temperature was taken by inserting the bulb of the thermometer through a small aperture in the gauze, so that it was situated in the mixture of air and ether vapour within the mask. It was noticeable that the lower temperatures were recorded when the patient's respirations were vigorous, and the higher temperatures when the breathing was quiet. The lowest temperature recorded was 80° and the highest 91°. *Boyle's machine:*—Gas, oxygen, and ether with limited rebreathing; the temperature of the mixture within the face-piece was 90 to 97°. *Closed circuit:*—Temperature within the face-piece was 92 to 95°.

The conversion of liquid nitrous oxide into a gas and of ether into a vapour are both associated with loss of heat, but the gas and vapour apparently at once acquire the temperature of their environment, and when inhaled are above room temperature, owing to their admixture with the warm exhaled gases. The results obtained in estimating the temperature of the inhaled mixture when the perhalation method is employed may give rise to some surprise. Presumably the important factor here is that 16 layers of gauze, with the entangled air, form a very efficient non-conductor of heat. It can be demonstrated that if a mask of this description is placed in position over the patient's face the temperature of the air within the mask rises in about two minutes from 73° (room temperature) to 87°, and in about the same time becomes saturated with water vapour. The formation of patches of snow is a phenomenon similar to the freezing of the skin with the ethyl chloride spray.

The body heat of the patient during anaesthesia was also studied.

The patient's temperature was taken in the axilla, first immediately before induction and then at frequent intervals—as a rule every 10 minutes. In short simple operations variations in temperature were negligible. A fall of from one to two degrees was noted in the more severe cases; occasionally there would be a rise of temperature. Duration of anaesthesia was in this respect an unimportant factor as compared with the nature of the surgical procedures. A particular study was made of the patient's temperature where open ether was the method of administration throughout the operation. There was quite definitely no fall in the patient's temperature on completing induction, and the temperature was maintained at the pre-induction level during lengthy operations not involving severe surgical measures. Colporrhaphies, for example, lasting 50 minutes, gave records such as 97.2°, 97°, 97.2°, 97.4°, 97.4°. As an example of a more severe operation, a panhysterectomy with difficult adhesions, duration 80 minutes, showed variations in temperature which were obviously associated with the surgical manipulations; before and after induction the temperature was 97.8°, falling after 50 minutes to 96.5°, and rising to 97.2–97.5° on closing the peritoneum. Partial gastrectomies and resections of bowel gave very similar figures. The most marked fall of temperature (from 98° to 96°) was recorded when the operation was an osteotomy of the femur, duration 90 minutes—anaesthesia, cyclopropane and ether, closed circuit.

Discussion

The maintenance of the patient's body heat during anaesthesia is an important matter, but it would appear that in this respect the influence of the temperature of the inhaled anaesthetic gases has been unduly stressed. According to the physiologists (Starling, 1941), in the adjustment of the temperature in man, regulation of the heat loss plays a greater part than heat production. Of the heat loss 80% is by the cutaneous circulation and evaporation of sweat, 11% by evaporation of water in the expired air, 4% in the liberation of carbon dioxide from the lungs, and 5% in warming *food* and air from 58° to 99° F. It is obvious that a very small percentage will be lost in warming up the air from 75° to 99°. Buxton (1914), quoting Kappeler, states that the body temperature is reduced 0.5 to 2.7° under ether. The body temperature is, however, susceptible to many different influences: it falls with loss of blood, and markedly so, in surgical shock. Many factors during an operation may influence the patient's temperature. It, moreover, is obvious that the warming of gases not only is unnecessary but is impracticable. The warmed gases would be at room temperature by the time they reached the face-piece.

Conclusions

It is not necessary to warm the gases or vapours when conducting inhalational anaesthesia.

Open ether should not be condemned as presenting a "cold vapour" to the patient for inhalation.

There is no evidence that general inhalational anaesthesia is associated with loss of body heat.

The variations in the patient's temperature during operation are due to other factors.

FOREIGN BODIES IN THE BRONCHI AND OESOPHAGUS IN CHILDREN

BY

B. M. L. ABERCROMBY, M.B., B.S., D.L.O.

Out of a number of cases of foreign bodies in the bronchi and oesophagus which have passed through my hands during the past five years it is thought that the following five are worth reporting as they illustrate various points which may materially affect the ease or difficulty with which these bodies may be removed.

Foreign bodies are less common in the bronchi than in the oesophagus. On account of the more rigid structure and small diameter of the bronchus, especially in children, removal is always more difficult in these cases. Removal is also complicated by the fact that, unless the foreign body is impacted, it tends to move up and down the lumen of the bronchus with respiration and cough, thus causing irritation of the mucous membrane and producing a varying amount of oedema, which may ultimately occlude any view of the offending article. The lumen of the oesophagus is considerably larger than that of the bronchus, even in a child, and the walls are lax and distensible, providing more space for manipulation, which considerably facilitates the removal of a foreign body.

Case I

A male child aged 5 was admitted to hospital on April 24, 1944, with a history of having inhaled two glass beads three days previously. One of these he had subsequently coughed up before admission, and it had been retrieved. Several severe attacks of coughing were accompanied by partial respiratory obstruction, alarming enough for the practitioner in charge of the case to send the child to hospital. On admission the patient appeared comfortable and continued so as long as he remained in one position. Any change, however, tended to bring on an attack of coughing, which at times was accompanied by signs of dyspnoea. This was explained, and subsequently demonstrated at the time of removal, by the bead being forced up into the trachea and impinging on the lower surface of the vocal cords. There were no signs of collapse of the lung, and *x*-ray examination revealed the bead situated in the left main bronchus.

Operation was performed under chloroform anaesthesia and the 25-mm. Irwin Moore bronchoscope passed down into the bronchus. The glass bead was easily visible in the bronchus, and was propelled up and down the lumen with each act of respiration. Attempts to seize the bead were found difficult for two reasons: (1) the extremely smooth surface of the bead, which allowed of no firm grip; and (2) although the bead was not impacted, there was hardly enough room to pass the forceps ends over it on either side in order to grip it. After several unsuccessful attempts the patient began to come round and the tube was withdrawn. While this was being done he coughed, and the bead was seen to be propelled into the trachea up against the lower surface of the cords, but before the forceps could be reintroduced it had been sucked back again into its original position. Under deeper anaesthesia the tube was reintroduced and a cotton-wool swab soaked in adrenaline held against the mucous membrane around the bead for a few seconds. This resulted in shrinkage of the tissues, and after one or two more attempts it was possible to secure a firm grasp of the bead and withdraw it into the lumen of the bronchoscope, and then to withdraw the whole. Further examination showed no damage to the bronchial mucous membrane. Beyond a slight laryngitis for a few days, the child suffered no ill effects, and was discharged about a week later.

Case II

A boy aged 3 was admitted to hospital on Jan. 9, 1945, at 3.30 p.m., having swallowed an open safety-pin at midday. Immediate *x*-ray examination showed the pin, open end downwards, lodged in the oesophagus just below the post-cricoid region (Fig. 1).

The interest in this case lies in the fact that the safety-pin had passed into the oesophagus point downwards—a very unusual occurrence, but one which considerably facilitates the removal. It is interesting to compare this case with the one reported by Mr. Ritchie Paterson in the *Journal* of Feb. 17, 1945, in which the pin entered the oesophagus point upwards. Mr. Ritchie Paterson described the dangers associated with the removal of a pin in this position and the dexterity required to effect this without perforating the oesophageal walls, with the possible consequence of mediastinitis.

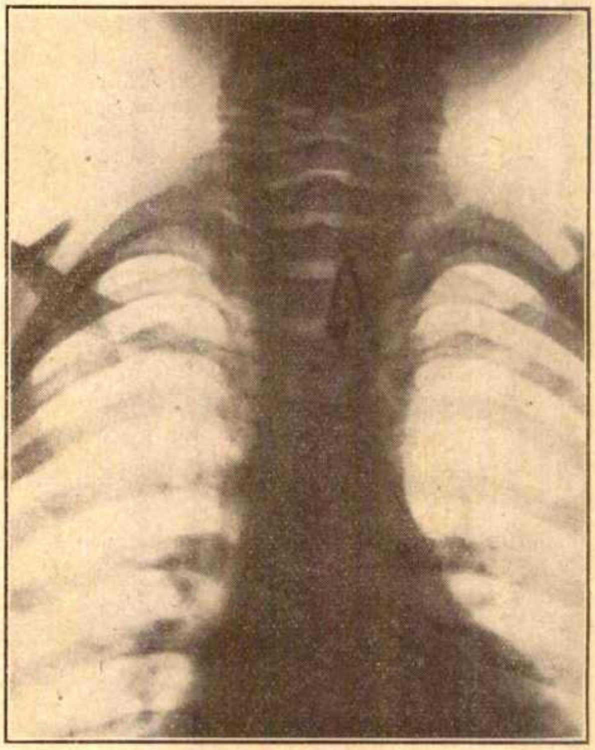

FIG. 1

In the present case, on introduction of the oesophagoscope under general anaesthesia, the pin was seen lightly poised on the posterior wall of the oesophagus. The point had presumably been caught between two folds of the mucous membrane without actually perforating the tissues. It was an easy matter to seize the rounded end with the forceps and withdraw the pin into the lumen of the tube and then to remove the oesophagoscope and its contents in one act. There was no damage to the tissues, and the whole operation, including demonstrating to the nursing staff, took at the most five minutes. The patient was sent home next day, none the worse.

Case III

On Jan. 9, 1943, a girl aged 14 was admitted complaining of cough and pyrexia for two weeks before admission. Clinical examination showed signs of collapse of the right lung. Skiagrams of the chest revealed a very large paper-clip, with a round head and two prongs, lodged head downwards at the bifurcation of the right main bronchus (Fig. 2). Each prong of the clip was later found to be 3/4 in. long. A preliminary bronchoscopic examination was done under chloroform anaesthesia, as it was thought that a good deal of pus and oedema might be present and preventing a view of the clip, thus interfering with its removal by direct vision. This surmise proved correct, and even with gentle pressure with a long wool-carrier the foreign body could not be felt. It was therefore decided to defer any further attempt at removal until this could be done under the *x*-ray screen. Owing to the disproportion in size between the diameter of the bronchus and the length of the prongs, it was obviously impossible to manipulate the clip so as to remove it with the points dangling and thus avoid damage to the mucous membrane. The only hope was to attempt to seize the prongs about half-way down their length, close them as much as possible and draw them into the lumen of the bronchoscope.

The patient was laid on the *x*-ray table and chloroform anaesthesia induced. A further examination through the bronchoscope proved the clip still invisible by direct vision. Under the screen, however, it was clearly seen, with the head firmly lodged down the right main bronchus. A pair of forceps was then passed down the tube to the clip and several attempts were made to secure a hold of both prongs together, but these were not successful. It was felt that the clip must be removed at all costs, even at the risk of damage to the surrounding tissues. A firm grip of one of the prongs was therefore obtained and gentle traction applied. This was accomplished only after turning the child on her right side. Watching all the time through the screen, the clip was pulled up for about an inch. It then stuck, and it was seen that one prong had caught in the tissues. Further gentle traction showed that this prong was acting as a fulcrum round which the head was rotating. Traction was therefore continued, and the prong, with its point embedded, was seen to be gradually bending at its centre. Traction was continued till the prong was bent double and no further progress was being made. Then, still with a firm grip on the first prong, a slight downward push was made in an attempt to dislodge the point. This was successful, and by a stroke of luck the now-doubled prong entered the lumen of the bronchoscope when further traction was applied. Thereafter it was a comparatively easy matter to draw the whole clip into the tube and withdraw the latter and its contents in one movement. The proceedings were viewed the entire time through the *x*-ray screen, and it would have been impossible to remove the foreign body without the vision thus afforded.

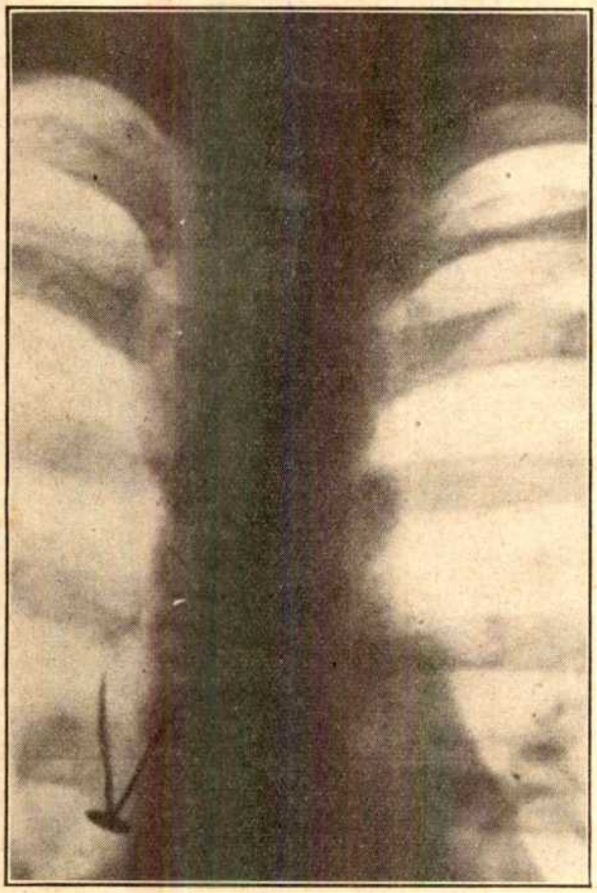

FIG. 2

The patient subsequently developed, not surprisingly, a complete collapse of the right lower lobe and a swinging temperature for a while, but with the help of sulphapyridine and breathing exercises she made a satisfactory recovery, and was discharged from hospital on March 25, 1943, to attend the chest clinic as an out-patient.

Case IV

A boy aged 12 was admitted on April 30, 1945, with a history of having swallowed or inhaled a bent pin which he had been holding between his teeth in an effort to straighten it. The patient was not distressed in any way and there were no abnormal physical signs. *X*-ray examination showed an apparently straight pin lodged in the commencement of the right main bronchus. An ordinary white steel pin similar to that involved was seen to have some ornamentation of an orange-coloured composition material around the head.

The child was placed on the operating table and chloroform anaesthesia induced. On introducing an Irwin Moore bronchoscope into the right bronchus one-half of the pin could be easily seen. With a little manipulation the ornamented head end came into view on the right, and it was seen that the pin was in fact bent into a "V," as stated by the child, though this was not apparent on the films. Having ascertained the shape and position of the pin, forceps were introduced and a firm grip obtained as near the point as possible, which was then drawn into the lumen of the tube. The decorated head of the pin impinged on the rounded end of the bronchoscope. This was then gently withdrawn without any difficulty till the subglottic region was encountered, when there was a slight hitch; but a little manipulation sufficed to withdraw the pin past the vocal cords, after which there was no further difficulty.

Other than a moderately severe laryngitis for a few days after the operation there were no ill effects, and the child was discharged fit on May 7.

Case V

A baby aged 18 months was admitted at 10 p.m. on May 19, 1945. The mother said she thought the baby had swallowed a piece of bone or button—"there were plenty of bits on the floor." Immediate *x*-ray examination revealed a shadow about the post-cricoid level, but it was difficult to be sure whether it was in the air or the food passage. From an oesophagoscopy performed under general anaesthesia it was evident that there was no foreign body in the oesophagus. Bronchoscopy was then attempted, but, owing to a misunderstanding as to the age of the child in the first place, the smallest-sized bronchoscope was not available, and the next size was too large to pass through the glottis without undue force, which would have damaged the cords. A brief glimpse was obtained, however, of the upper part of the trachea, but no foreign body could be seen. The child was breathing comfortably and was in no way distressed, so it was decided to postpone further examination till another skiagram could be taken the next day. This was done, and a lateral view showed a small pointed body at the level of the sixth cervical vertebra, but it was still not clear whether it was in the bronchus or the oesophagus. A barium meal was therefore given, and it immediately became clear that the offending article was in front of the oesophagus in the left bronchus, possibly exerting slight pressure on the oesophagus.

The baby was taken to the theatre and chloroform anaesthesia induced. The smallest-size Negus bronchoscope was then introduced through the larynx with the aid of a Mackintosh electrical laryngoscope. Owing to the small lumen of the tube the view was very restricted, but by keeping well to the left side of the trachea the bronchoscope passed easily into the left main bronchus. After sucking away some mucus there appeared to be a small dark hair-line across the lumen of the bronchus, which could not be sucked away and was presumed to be the foreign body, although no adequate view could be obtained. A very fine pair of forceps was introduced down to the site and gentle palpation performed, when something hard could be defined. The forceps were opened and manipulated till it was felt that a grip on the hard body had been obtained; traction was then exerted until the forceps ends and their contents were within the lumen of the bronchoscope. The latter and its contents were then withdrawn in one movement. On examination the foreign body was seen to be an irregular piece of button of some composite material, approximately half an inch long and a quarter-inch in diameter.

Beyond slight pyrexia for a few days the baby suffered no ill effects, and was discharged from hospital on May 25.

I am indebted to Dr. W. E. Crosbie, medical superintendent of Alder Hey Hospital, for permission to publish the above cases, and to Dr. Bennett-Jones for the anaesthetic in Case III and Dr. Derham in the four remaining cases. I have also to thank the radiographer, Mr. Lucas, for the *x*-ray films and prints and his valuable assistance in screening the patient in Case III.

AN UNUSUAL CASE OF ERYTHROBLASTOSIS FOETALIS

BY

E. F. AUBERT, M.D.

J. B. COCHRANE, M.B.

AND

M. E. ELLIS, M.Sc.

The possibility that erythroblastosis foetalis may sometimes be due to a heterospecific pregnancy (i.e., to maternal anti-A or anti-B iso-agglutinins) has been considered by Wiener (1943); and Boorman, Dodd, and Mollison (1942, 1944) have reported three cases in which this seemed to have happened. A fourth and rather striking case has been investigated by us, with the following findings.

Clinical History

Mrs. A., a primigravida aged 24, attended the antenatal clinic at the City Hospital, Nottingham, on Jan. 28, 1944, and was seen by one of us (J. B. C.). Her L.M.P. was Sept. 29, 1943, and her fundal height at 14–16 weeks corresponded with the period of amenorrhoea. She was found to have an intermediate degree of pelvic contraction, but otherwise her general condition was satisfactory. When aged 9 years she had had scarlet fever complicated by acute rheumatism, but was nursed at home and was off school for three months, apparently making a complete recovery.

She attended the ante-natal clinic regularly throughout and, apart from the failure of the head to engage at the 36th–38th week, her condition was entirely satisfactory and normal in every respect. Arrangements were made to admit her on July 3, 1944, three days before the expected date of confinement, for investigation of the pelvic contraction. She was admitted in labour to hospital on July 1—approximately at term. The foetus was in the vertex left occipito-lateral position and the head poorly flexed and mobile: no hydramnios was present.

On admission skiagrams for foeto-pelvic disproportion were taken and, as no disproportion seemed to be present, it was decided that she be given a trial labour. After a first stage of labour lasting just over 22 hours, and a second stage of two hours, it was found that the head remained arrested in the transverse diameter of the pelvis at the level of the ischial spines.

Under spinal anaesthesia a live mature male infant with gross hydrops foetalis was delivered by manual rotation and forceps. It weighed 7 lb. 2 oz. and was 17¼ in. in length. After birth the infant's colour and cry were both very poor, and remained so despite lobeline injected into the umbilical vein. The infant died 25 minutes later.

The placenta and membranes looked normal, did not show any of the typical macroscopic features generally associated with such a foetus, and weighed 21 oz.—a normal ratio in weight to the infant. At delivery blood was taken from the umbilical cord for investigation, the results of which are given below.

Necropsy of the infant showed gross oedema of all the viscera, with much free greenish fluid in all the serous cavities. The lungs were surprisingly well aerated though markedly oedematous, and apparently had been expanded as fully as was possible under the circumstances. The liver and heart appeared normal, but the spleen was large, though normal in shape. No evidence of injury to the meninges or of intracranial haemorrhage was found, but the brain was very oedematous and much more friable than normal. The thymus was also much larger than normal, although its consistency was not apparently altered. Pieces of liver, thymus, spleen, sternum, and a lymph node were sent for histological examination, and these showed the very characteristic histological picture of erythroblastosis foetalis.

The patient made an uninterrupted recovery and was discharged on July 17. She was seen at the post-natal clinic on Aug. 15, when her condition was satisfactory from an obstetric point of view. She was asked to return in four weeks' time for further serological investigations, but has so far defaulted.

Serology

Father's blood—Group A Rh-negative. Mother's blood—Group B Rh-negative. Foetal blood—Group A Rh-negative. No irregular iso-agglutinins were found in the mother's serum, but her anti-A titre—determined against A_1 cells of average sensitivity by the method of Taylor and Ikin (1939)—was 16,000,000. Anti-A was looked for in a sample of foetal blood (obtained from the cord) and was found present to a titre of 128. Despite the presence of this anti-A in the foetal plasma, the foetal erythrocytes were not agglutinated; we think that this may have been due to the gradual elimination of the more sensitive foetal red cells (i.e., those containing substantial amounts of A substance) by the powerful maternal anti-A iso-agglutinin, since the foetal red cells were relatively insensitive to anti-A sera, and were agglutinated by the maternal anti-A only to a titre of 1024. The husband's cells were agglutinated to a titre of 250,000 by the mother's serum.

On Aug. 8, five weeks after delivery, the maternal anti-A titre was 4,000,000. Unfortunately, it was not possible at the time to determine the A subgroups of husband and baby owing to lack of the necessary sera. As the patient failed to attend again no further serological investigations were possible.

In view of the extraordinarily high maternal anti-A iso-agglutinin titre, and of the presence of Anti-A in the foetal blood, it is difficult to avoid the conclusion that this was a case of erythroblastosis foetalis due to heterospecific pregnancy.

Our thanks are due to Dr. W. R. Harvey, Royal College of Physicians Laboratory, Edinburgh, for the histological report, and to Dr. C. L. Crawford Crowe, medical superintendent, City Hospital, Nottingham, for permission to publish this case.

Medical Memoranda

Full-term Extra-uterine Pregnancy associated with Extensive Prolapse

The following case shows many points of interest in addition to its rarity. There was complete lack of symptoms pointing to an early emptying of the uterine contents into the abdominal cavity. Toxaemia occurred at 36 weeks' gestation. The persistent transverse lie and extensive prolapse were aids to the diagnosis.

Mrs. P., 7-para, aged 41, first reported to the ante-natal clinic when four months pregnant. Her past obstetrical history was as follows: the first two children had been born prematurely at eight months, the first surviving 7 weeks and the second 2 days; she then had four normal pregnancies and labours, all the children being alive and healthy.

At her first attendance at the clinic her only complaint was of "dropping of the womb." On examination the fundus was enlarged to the size of a 16-weeks pregnancy, and on vaginal examination an extensive prolapse, with slightly eroded cervix, was present. The cervix was disinfected, pushed up, and a large ring pessary inserted. The date of her last period was rather uncertain; but there had been no irregular bleeding or pain, and the estimated date of delivery worked out at about the middle of March.

The pregnancy progressed, but the ring pessary was unsatisfactory because it failed to keep the prolapse in position and failed to stay in the vagina for any length of time. As the cervix was now more ulcerated and bleeding, it was decided to admit the patient to hospital. Improvement occurred after admission on Jan. 19, 1945, and while she was in bed the prolapse was not evident except after a bowel action. As the patient had another two months to go before full term, a Napier's pessary was fitted and she was discharged with suitable instructions. She was then very much more comfortable, but had to be readmitted a month later—Feb. 19—with toxaemia of pregnancy. There was gross pitting oedema of feet and legs, the B.P. was 182/110, and the urine contained a trace of albumin. After a week's rest in bed the B.P. had fallen to 140/88 and the urine was clear. The oedema had improved but not quite disappeared.

The foetus at this stage was lying in a transverse position high up in the abdomen. When version was attempted the foetus immediately reverted to its former position. An *x*-ray examination was carried out and the following report obtained: "This is a single pregnancy, transverse presentation, spine upwards, the head being opposite and above the level of the left iliac crest. The biparietal diameter is estimated at 3.6 in."

It was suspected that we might be dealing with an extra-uterine pregnancy or that the placenta might be occupying the lower uterine segment. However, before further investigations could be carried out the patient started to have violent abdominal pain, with vomiting and rapid rise in pulse rate. The pain seemed to be localized at first to the right iliac region, and there were no palpable uterine contractions; but the pain and tenderness rapidly became generalized over the abdomen, together with rigidity of the rectus muscles.

A laparotomy was obviously indicated, and when the patient was anaesthetized with cyclopropane the contour of the abdominal swelling was seen to be quite irregular, and, the muscles being relaxed, foetal parts could be felt very easily. An incision was made in the midline below the umbilicus, and a thin-walled bluish sac presented at the wound with the foetus plainly visible inside. A live male baby was delivered; but, unfortunately, in spite of all efforts at resuscitation, he died about an hour later.

The umbilical cord was about 18 in. long and its distal half was divided into two separate vascular bundles, which entered the placental mass separately. The latter had an extensive attachment in the pelvis, the peritoneal surfaces of the bladder, caecum, enlarged uterus, and broad ligaments being involved. Separation of the placenta, tentatively tried at one spot, was easily effected, and the whole placental mass was removed much in the same way as an adherent placenta is removed from the uterus. No attempt was made to pick up bleeding-points, but the whole bed from which the placenta had been removed was packed with a length of wide ribbon gauze, the end of this being brought out through the lower part of the abdominal incision. The packing was removed 24 hours later under gas anaesthesia, and the opening through which it came was closed.

The patient had a happy convalescence and was able to go home 18 days after her confinement.

G. E. Morris (*New Engl. J. Med.*, 1945, **233**, 180) states that multiple ulcers of the legs are often due to infestation of the clothing with body lice, especially in the middle-aged. Search for each parasite therefore should be made in all suspicious cases.

Reviews

PUBLIC MEDICAL CARE

Public Medical Care: Principles and Problems. By Franz Goldmann, M.D. (Pp. 226. $2.75 or 18s. 6d.) New York: Columbia University Press; London: Oxford University Press. 1945.

The object of this book cannot be better stated than in its own words: "an attempt to give a complete picture of public medical care as a social movement." The author, as associate clinical professor of public health at Yale and lecturer in the New York School of Social Work, is well qualified to make this attempt. Mr. Gradgrind used to say, "What I want is facts." This book would have satisfied him, for it is full of relevant facts derived from almost every civilized country. Great Britain is freely drawn upon for both facts and historical derivations. Equally important is the critical examination of these facts and of the tendencies they disclose. Public medical care in the U.S.A. has had a long and tortuous history, as it has had here. Dr. Goldmann traces its American development back to the English Poor Law system, through the poor-house, the lunatic asylum, the clinics arising from charitable dispensaries, the rise of the general hospital, and the gradual transfer of responsibility from voluntary agencies to larger and larger political units. This is a familiar picture to British students of the subject, and Dr. Goldmann's comparisons and analogies will be found useful everywhere. Running through the U.S.A. picture are, however, complications from which we have been happily spared, caused by the existence of 48 States, jealous of their independence and only reluctantly consenting to transfer responsibility to the Federal authority even where central control is obviously needed.

The familiar factors—free choice of doctor, means tests for insurance, whole- or part-time doctors, group practice, etc.—are all there, and the author deals with them judicially. There is a good deal of the "on the one hand—on the other hand," but it is evident that on balance Dr. Goldmann is impressed with the administrative convenience and the smaller liability to abuses of the salaried doctor. He is emphatic that the administration, at all events, of medical care should be in the hands of salaried medical superintendents, and has some revealing remarks on the still existing tendency in some areas to put "political pets" into these positions.

As regards health insurance, he is against any "means test," which he says has the disadvantage that it discourages the more deserving from applying, often till it is too late to prevent serious complications or life-long disability. Summing up the various methods of dealing with medical insurance, he is of opinion that the Russians have the only logical plan, though he realizes that it is often impossible to make any progress if one insists on strict logicality—and this certainly applies in the U.S.A. He grants that "under such a system most or all of the members of the health professions would become civil servants, and that private practice if allowed to continue would have to rely on the demand and purchasing power of a relatively small fraction of the population. Those [medical care functions] owned by the non-governmental organizations, if legally permitted to operate, would be faced with constant financial difficulties and would gradually disappear." The bearing of this forecast on problems now facing the British profession will not be overlooked. The book can be cordially recommended to all who desire to study these problems with as wide a background as possible.

THE TISSUES OF THE BODY

The Tissues of the Body. An Introduction to the Study of Anatomy. By W. E. Le Gros Clark, F.R.S. Second edition. (Pp. 388; illustrated. 21s.) Oxford: At the Clarendon Press. 1945.

Notwithstanding the continuance of the great war from 1939—the year when *The Tissues of the Body*, by Prof. Le Gros Clark, was first published—until 1945, the date of issue of the second edition of this book, a very considerable amount of important research in anatomy has been accomplished. This work has been concerned with problems having a distinct practical bearing, and includes, among other researches, special studies on the regeneration and repair of striated muscle and on the nerve- and vascular-supply of muscle, and also detailed descriptions of the vascular patterns and innervation of blood vessels in animals. The solution of some of these problems had been in progress before 1939, and much of the recent work recorded or referred to in the new edition has arisen from questions which have emerged as a direct outcome of the initial stages of these investigations—for example, the restoration of function of muscles or nerves deprived respectively of their nerve- or vascular-supply. To indicate the type of work referred to, one may mention the effects of re-innervation of paralysed muscles by *sensory* nerve fibres, which has now been conclusively shown by Gutmann to be ineffectual with regard to restoration of their motor function, since atrophy and fibrillation of the muscle proceed in the same manner as in cases in which the motor nerve has been divided and no re-innervation has been attempted. In re-innervation of striated muscle by a *sensory* nerve, even when new sensory fibres succeed in reaching motor end-plates, no connexion is made with these, and sensory fibres are unable to form new end-plates; moreover, stimulation of the grafted sensory nerve does not make the muscle contract. In line with the above example is the demonstration, by methylene-blue injections, of the existence of interconnexions by arterial anastomoses between the branches of intramuscular vessels arising from different sources; though uncertainty exists about the establishment of efficient immediate intramuscular anastomoses with complete regeneration of partially devascularized or injured muscle, which result has lately been demonstrated by the author in conjunction with L. B. Blomfield.

Besides additions to the text recording progress in anatomical research work, a considerable number of excellent new illustrations have been added, and the new edition fully maintains the high standard and practical character of the book.

PERSUASIVE PSYCHOTHERAPY

Active Psychotherapy. By Alexander Herzberg, M.D., Ph.D. (Pp. 152; 12s. 6d.) London: Research Books Ltd., in association with William Heinemann Medical Books.

Nearly all psychotherapists now agree that treatment of the psychoneuroses and sexual maladjustments must rest on an analytical basis, though they are not agreed as to which of the various analytical methods is the best to use. All, however, are conscious of the need to shorten and simplify all existing methods of treating these forms of mental illnesses, since at present such treatment takes a very long time and there are too few psychiatrists to do the work, and far too many patients who require help.

This book is a description of the methods of a very experienced psychotherapist who worked for many years in Berlin, before he had to leave and come to this country, where he found opportunity to continue his work at University College, London. He, in common with others, uses analytical methods as the basis of his treatment, but has devised a method of imposing tasks upon the patient with the idea of shortening the course. These tasks require efforts of will on the part of the patients to which they have been persuaded by the author. It seems remarkable that they should submit to some of these tasks, since they involve such things as giving up an object of love, forcing themselves into situations of which they are terrified, and so on. It speaks much for the persuasiveness of Dr. Herzberg and for the influence he exerts over his patients that he can make some of them carry out these tasks; but it is doubtful if all psychotherapists could aspire to this persuasiveness, or that all patients would find themselves able to carry out the instructions, however they might wish to do so. Nevertheless, when success is attained, there is no doubt whatever that treatment will be very much shortened and more lasting success achieved, since the ability to carry out the tasks almost amounts to cure.

This book is certainly worthy of careful study by all psychotherapists, as there is great promise in Dr. Herzberg's methods if they can be carried out; but those who are not fully acquainted with the difficulties and complexities associated with the treatment of the psychoneuroses and sexual perversions must not expect that a new short method of therapy of universal application has been discovered.

CHEMICAL DISCOVERIES AND ECONOMIC LIFE

This Chemical Age. The Miracle of Man-made Materials. By Williams Haynes. (Pp. 288. 12s. 6d.) London: Secker and Warburg. 1945.

This book is mainly a historical narrative of the developments of chemistry in the economic life of the world. It is written in a bright and racy style such as may well attract readers who are not acquainted with the science or technology of chemistry. Indeed, in the preface, which is entitled "A Word with the Reader," the author says: "I am rather proud how little chemistry there is in this book, which deals with all the new synthetic chemical products." Yet the contents are informative in a high degree to those who are trained chemists, and the volume will be found good by students of chemical history.

The lively and vigorous treatment of the facts of history makes entertaining reading, and the author is to be commended for the thoroughness with which he has explored the available sources of information and for the acute insight which has enabled him to reconstruct pictorially the background and environment of episodes which were critical in the history of discovery. Nothing appears to have been omitted that has or has had an interest to the public who have benefited by chemical discovery. The author has brought his history to the present day, and only finished a little too soon for a discussion of the atomic bomb. His comments on the political and economic effects of chemical discoveries are also shrewd and far-seeing. The discussion covers dyes, synthetic textiles, perfumery and flavouring agents, the sulphonamides and chemotherapy, synthetic rubber, plastics, the influence of chemistry on warfare, and a great number of other subjects, all written in a flowing sequence that makes easy reading. The addition of a glossary under the title "Words that Puzzle," and a very full index, completes a useful book.

A YEAR'S PROGRESS

The Medical Annual, 1945. Edited by Sir Henry Tidy, M.D., F.R.C.P., and A. Rendle Short, F.R.C.S. (Pp. 410. 25s.) Bristol: John Wright and Sons Ltd.

In our last review of this publication we suggested that "the usefulness of the volume as a whole would be much improved by a yearly article under the heading of 'Vital Statistics.'" Whether the Editors acted on this hint, or arrived simultaneously at the same conclusion, an article under this heading by Dr. Percy Stocks now appears and fills "an obvious gap." It is intended to make a review of this subject a yearly feature. As the Editors say, ". . . statistics are invading the life of the medical profession," and statistics is something the doctor, as a practical biologist, does not take kindly to. Yet medicine is becoming more and more a matter of exact measurement, and many an investigator in the past—and in the present—would have been saved endless trouble if he had first of all planned his investigation with a medical statistician at his elbow, and had submitted his observations to the same exact, and exacting, eye before committing himself to print. A very full review on penicillin fills in another gap left in the last *Annual.* "D.D.T." is referred to under the heading of "Pediculosis," but this is hardly a measure of its importance, and we can trace no reference in the edition now before us to its use in the control of malaria. A separate article on insecticides and insect-repellants would seem to be needed to put this subject into proper perspective.

The *Medical Annual* has always included a number of illustrations which relieve the bleakness of the printed page, but nevertheless to devote two coloured plates to depict the pinhole meatus, and yet a third to show up the meatal ulcer of infants, seems to be out of proportion; and does the coloured plate demonstrating gangrene of the toes in the condition of "immersion foot" say something that cannot equally well be said in a less paper-consuming way? More informative, we believe, would be the use of isotype illustrations to put statistical matter in a visual form easily grasped by the mind which boggles at numbers and formulae.

Needless to say, this year's *Annual* bears all the usual marks of careful editorship and indexing, and for the many now returning from the Forces to civil life should prove to be an indispensable reintroduction to current medical practice.

Notes on Books

We have received from the Library of the U.S. War Information (1, Grosvenor Square, London, W.) a collection of articles reprinted from *War Medicine* under the general heading *Convalescent Medicine,* the subdivision being devoted respectively to physical therapy, occupational therapy, and emergency treatment of acute war neuroses; also *Tuberculosis,* a collection of articles in two volumes reprinted from various American periodicals, the first volume relating to diagnosis and the second to treatment. These three assembled reprints may be seen at the Library of the British Medical Association.

Clinical Case-Taking, by G. R. HERRMANN (Henry Kimpton; 9s.), of which a third edition has now appeared, gives a compact and detailed account of history-taking and physical examination. Prof. Herrmann believes that a thorough examination of a few patients is a better discipline for the student than a superficial glance at a large number. His book sometimes reads like a drill manual, but there is a great deal to be said for a well-drilled student.

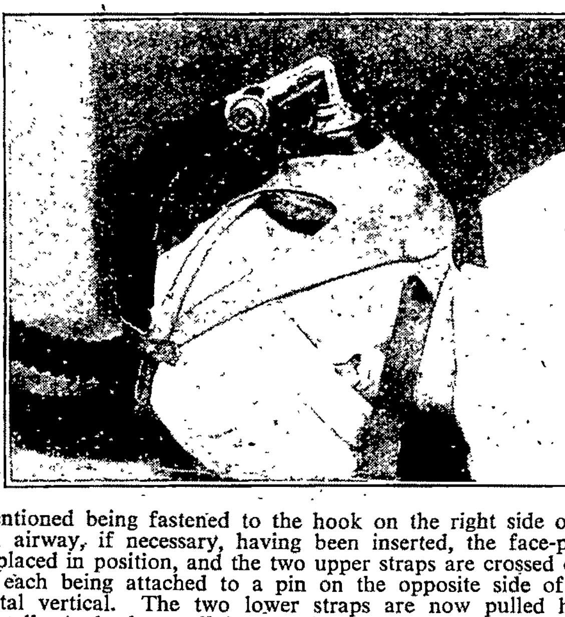
Preparations and Appliances

A COMBINED HARNESS AND TUBING SUPPORT

Dr. HARVEY NICHOL, honorary anaesthetist, Royal Gwent Hospital, Newport, Mon., writes:

Whereas in most cases the harness in common use will retain the face-piece satisfactorily in position, it is sometimes necessary to support the jaw with the hand in order to obtain an unobstructed airway, especially if the face-piece is strapped on tightly enough to ensure a gas-tight fit, as is essential if a completely closed circuit is to be maintained or a "draw-over" principle is being employed. Also the heavy circle type of absorber tubing tends to pull the face-piece out of position.

The apparatus illustrated is composed of a harness made of rubber and a metal L-shaped portion, on which the patient's head rests and to which the harness and tubing are secured. The harness is shaped to fit closely round the chin and face-piece, and has five straps attached to it. The single strap attached to the left side of the harness is threaded through two lugs on the distal end of the horizontal part of the tubing support, which is then placed under the patient's head. The harness is now brought into position under the chin, the free end of the strap mentioned being fastened to the hook on the right side of it. An airway, if necessary, having been inserted, the face-piece is placed in position, and the two upper straps are crossed over it, each being attached to a pin on the opposite side of the metal vertical. The two lower straps are now pulled horizontally, and when sufficient tension has been applied to give a free airway these are also fastened to the pins already mentioned. Finally the end of one (or each) of the latter straps is made use of to support the tubing by passing it over same and fixing to the pin on the opposite side.



When thus adjusted the jaw is supported, the face-piece held in position with a gas-tight fit whatever the contour of the face, and the tubing does not drag on the face-piece. A good airway is assured, and the patient can be moved into any position without displacing the face-piece or tubing.

The apparatus was made for me by Messrs. Coxeter and Son, Ltd., in conjunction with Messrs. A. Charles King, Ltd.

MICROBIAL ANTAGONISMS

Few users of penicillin are aware that its development as a chemotherapeutic agent was the culmination of a long series of studies on microbic antagonism going back more than sixty years. Yet this is the theme of the Lister Memorial Lecture delivered by Sir Howard Florey to a large audience at the Royal College of Surgeons on Oct. 11 and printed in our present issue. To many people the idea that one micro-organism may attack another presented itself first in the fully developed and highly refined form of penicillin, but in fact this sort of antagonism was fully recognized even by Pasteur himself, and very numerous examples of this phenomenon were brought to light even between his time and the end of the last century. The lecturer's diligent search of the older literature has revealed a whole series of observations covering a wide area of the field of microbiology which together make a fascinating story.

The use of one micro-organism in an attempt to eliminate infection by another has taken several forms other than that with which we are now generally familiar. Two of them are in reality methods of immunization, involving either the administration of preparations of one micro-organism in order to excite active immunity against infection by another, or the lysis of the specific micro-organism by an extract of another in order to produce a sort of dissolved vaccine—the "mycolysate" of Gratia. These methods involve a different principle and mechanism, but those which depend directly on microbic antagonism—the power of one micro-organism to attack another—are also of two kinds. The less familiar of these is replacement therapy—the introduction of a living micro-organism into the body with the intention that it shall displace another. Thus there is some evidence that staphylococci can displace diphtheria bacilli; the introduction of pneumococci has been suggested as a measure to dislodge meningococci from the nasopharynx; there is even the suggestion that one strain of *Bact. coli* can advantageously be used to eradicate another. This and the use of *L. bulgaricus* or *L. acidophilus* in an attempt to change the flora of the alimentary tract must be viewed in a somewhat different light from the attempted replacement of definite pathogens causing actual infection.

All these proceedings, throughout the long history of such studies, are subsidiary to the use of microbic extracts as antiseptics. That some micro-organisms form substances lethal to or inhibitory to the growth of others has been fully recognized since 1885, and only two years later than this we see the first use of the method of adjoining streaks on plates of solid media, whereon the growth of one micro-organism prevents that of another within a zone in which the antagonizing substance diffuses. Nor was it long before the study of these substances came to embrace moulds. Further still than this, a mould extract was used therapeutically over thirty years ago: Vaudremer employed an extract of *Aspergillus fumigatus* in the treatment of over 200 cases of tuberculosis between 1910 and 1913. It is of peculiar interest that this fungus has quite recently been shown to produce several distinct and very potent antibacterial substances, one of which certainly has the action on the tubercle bacillus *in vitro* which Vaudremer claimed for his extracts, although the possession of this property is unfortunately far from guaranteeing any therapeutic powers. Even the word "antibiosis" was coined as long ago as 1889; hence "antibiotic" as a noun generally descriptive of all such substances has at least the sanction of precedence, and, however inappropriate it may seem, it has evidently come to stay.

The history of the discovery of such substances as this, including the outstanding one of penicillin itself, pursues an almost unbroken course from 1885 to 1940. Many were used therapeutically as antiseptics. One, pyocyanase, became an article of commerce and was extensively used on the Continent for many years. As Florey points out, the new era in antibiotic therapy was ushered in by the work of Dubos on gramicidin. The properties and powers of this substance were systematically investigated. It was chemically characterized and shown to be capable of exerting a systemic effect, although it was too toxic for therapeutic use of this kind. We are led to infer that the example of Dubos encouraged Florey and his colleagues to undertake a similar systematic investigation of penicillin, with what results the world is now well aware. That it proved to have such unheard-of properties—to be not only a true chemotherapeutic agent in the sense of exerting a systemic affect, but almost devoid of mammalian toxicity and singularly indifferent to the adverse conditions which prevent the action of so many other antimicrobic agents—all this was more than anyone could have expected. But these properties were conclusively demonstrated and the foundation laid for production on an industrial scale. It is indeed appropriate that a lecture commemorating Lister should deal with the modern apotheosis of the method which he founded.

Not the least entertaining part of the Lister lecture is that in which Florey describes the present microbiological "gold rush," as he calls the search after new antibiotics which has followed the penicillin revelation. How extensive this search has become and how wide the net is being cast few people can realize who do not closely follow the literature. The most promising genera of fungi have been systematically studied by many investigators, and many antibacterial substances produced by them have been identified. A good idea of their distribution among different genera may be gained from the painstaking studies of Wilkins and Harris,[1] who have now examined 400 species. The same authors[2] have examined 700 species of the larger fungi, while a start has been made on the higher plants by Osborn[3] and on a smaller scale by Huddleson *et al.*[4] Russian authors[5] have discovered mysterious virtues in the vapour emitted by crushed onions and other plants, which they call "phytoncides." Also from the Soviet Union come reports[6] of a different and superior gramicidin. An alga is the source of chlorellin, the promising characters of which are described by Pratt *et al.*[7] It is an extraordinary fact that among all these substances, which must now run into thousands, not one has yet been found which improves on the therapeutic performance of penicillin without having some countervailing disadvantage either in toxicity or in the limitation of conditions for its activity. This is a field in which premature enthusiasm should be guarded against. The early therapeutic promise of patulin was not fulfilled, and the astonishing *in vitro* performance of notatin—a far more potent antiseptic under certain conditions than penicillin itself—has no therapeutic counterpart at all. Streptomycin, one of the few reasonably non-toxic fungus products which act on Gram-negative organisms as well as Gram-positive, and recently used for treating typhoid fever by Reimann *et al.*,[8] may perhaps break down, as Florey reveals here, for the simple reason of inactivation by changes in *p*H. There is no knowing where these studies may lead, and the complete conquest of microbic infection may yet be their culmination. The study of such agents has become a task for collaborative effort, in which perhaps the most important of several parts will have to be played by the biochemist. An idea of where such studies may lead may be gained from the work of Hays *et al.*[9] on what used to be called "pyocyanase." From extracts of *Ps. pyocyanea* cultures they have isolated no fewer than five crystalline antibacterial substances, one at least of which has very promising characters.

TRIUMPH AGAINST MALARIA

Now that the war is over, the security silence is being lifted and many scientific developments can be made known to the world at large. After the entry of Japan into the war and the loss of Java with its supplies of quinine, intensive research in the U.S.A. and this country was carried out on the control and prevention of malaria. Some of the results of this work have already been disclosed, others will appear in due course. One of the greatest triumphs was made public early this week, when the discovery of an extremely active new antimalarial compound in the laboratories of Imperial Chemical Industries was announced. The following account is based upon information acquired by the Medical Research Council during the development of this substance.

Early in 1942 a team of chemists and biologists began the search for a new synthetic antimalarial which could replace the lost supplies of quinine and which would prove more effective in preventing and treating malaria than this somewhat imperfect medicament. Antimalarial activity was found in several interesting types of chemical compounds, but no satisfactory result was obtained until 1944, when Mr. F. M. Rose, working in collaboration with Mr. F. H. S. Curd, synthesized a substance which was at first known by the code number M.4888. This was tested by Mr. D. G. Davey upon experimental infections of *Plasmodium gallinaceum* in chicks and on other forms of avian malaria, and was shown to be remarkably active in destroying malaria parasites; its toxicity for mice and similar small animals was relatively low. Clinical trials were initiated by Dr. A. R. D. Adams and Prof. T. H. Davey at the Liverpool School of Tropical Medicine, and its therapeutic activity was shown to be as great for naturally occurring human malaria as it was for infections in the laboratory. Later Dr. Adams was joined by Prof. B. G. Maegraith, who explored its pharmacology in volunteers and the way in which it was absorbed, distributed, and excreted by the body. Supplies of the compound were sent by air to Australia, where its action in preventing the development of malaria following exposure of volunteers to infected mosquitoes was investigated by a team at Cairns working under the direction of Brig. N. Hamilton Fairley. Other studies on various aspects of this compound are in progress in certain military hospitals in Britain, at the London Postgraduate Medical School, and in India.

Altogether the compound has now been given to over 200 patients. Until its use is more widespread any account of its action must be provisional. It is a white powder which does not stain the skin as does mepacrine. The chemical formula is not yet disclosed, but it is relatively simple and differs fundamentally from previously known antimalarials; the manufacture will be easy. When given by mouth the drug is rapidly absorbed. Excretion is somewhat slower, and on repeated twice-daily doses the plateau of the concentration in the plasma is not reached for several days. About a third of the dose is excreted in the urine. The compound is very well tolerated, and up to half a gramme can be given twice daily; the only untoward effect produced to date by larger doses has been signs of gastro-intestinal irritation, which might be avoided by subdividing the dose. So far the course of treatment has consisted of twice-daily doses for fourteen days. The smallest dose on this regime which will terminate a clinical attack of benign tertian malaria appears to be 10 to 50 mg., which is only about a fifteenth of the maximum tolerated dose. Unfortunately (as with quinine and mepacrine) relapses of benign tertian often occur, and even with large doses a quarter of the patients have relapsed. The response of malignant tertian malaria resembles that of benign tertian, but (as with other drugs) relapses are less frequent. The effect of the drug on quartan malaria has not yet been studied. If used to protect men against malaria, when exposed to infected mosquitoes, it has been found that 0.1 g. daily prevented all clinical signs of malaria in a small group of volunteers who were bitten by mosquitoes carrying *P. vivax*, although parasites were later demonstrated in a small proportion of the subjects. Apparently this antimalarial action is a suppressive one, exerted upon the trophozoites as soon as they appear in the erythrocytes. The action upon *P. falciparum* is more complete and there is less tendency for a latent infection to be acquired. Gametocytes are injured by the drug, but they are not completely removed from the circulation.

So far as can be seen from the information now available the new drug acts upon the same stages of the malaria parasite as does quinine or mepacrine, but there is a wider range between the minimum effective dose and the maximum tolerated one. The greatest need in malariology at present is a drug which will prevent relapses due to benign tertian malaria. Although not dangerous, these relapses are troublesome. The new compound certainly does not prevent all relapses; whether it prevents more or fewer than do quinine and mepacrine cannot be told until certain comparative trials now in progress are completed. It should be cheaper to produce than either quinine or mepacrine, and it is free from the drawbacks of the latter, which stains the skin yellow. As a suppressive, to prevent clinical malaria following exposure to infection, it seems to be equal or superior to mepacrine and much superior to quinine. Provided that widespread use reveals no occurrence of dangerous idiosyncrasies, such as agranulocytosis or nervous lesions, it may well displace quinine and mepacrine from general use in malarious areas.

Before congratulating Imperial Chemical Industries and the research workers concerned on this brilliant discovery, a minor criticism must be made against the nomenclature of the substance. "Paludrine" is an excellent euphonious word of obvious significance, but unfortunately it had already been applied to an earlier less successful product (compound M.3349) and as such had appeared in a medical journal.[1] For some time to come this use of the same name for two different substances will cause needless confusion, and the new product will have to live down the less favourable impression which may have been created by the older one. Apart, however, from this minor blemish, all concerned in this discovery deserve admiration and praise—the directors of I.C.I. for their far-sighted support of large-scale chemotherapeutic research, Messrs. Rose, Curd, and Davey for the actual discovery, and the clinical workers named above for their careful exploration of the medical uses of the new remedy which was placed in their hands. The whole story forms a good example of the team work which is necessary for progress under modern conditions. This latest success is valuable not only in itself but also as a proof that British brains and organization, when properly applied, can produce quite as great discoveries as those of Germany or of any other nation. With such encouragement it is to be hoped that this country will no longer delay in giving to research on chemotherapy and tropical medicine the support which our wide Colonial Empire requires.

RADIOTHERAPY FOR VASOMOTOR RHINITIS

Unless the antigen which produces the allergic symptoms of vasomotor rhinitis can be discovered treatment remains unsatisfactory. Even if the antigen or antigens are known, it does not follow either that they can be eliminated easily or that the patient can be desensitized. Local treatment by ionization, by cautery, and by vasoconstrictor drugs all have disadvantages, and the application of radium to the mucous membrane of the nose is an uncertain and dangerous measure. The suggestion that radiotherapy by means of *x* rays might prove effective is therefore worth serious consideration. Axel Renander[2] states that in 1936 experimental irradiation of the nose in a case of pronounced vasomotor rhinitis was followed by complete freedom from symptoms for eight months. Since then he has treated 400 patients in this way, and has recorded a series of 226 cases. He notes that Schmidt[3] reported on a favourable result in a case of hay-fever as long ago as 1915, but very few systematic attempts have been made to ascertain the value of this treatment. Of the 226 patients, 126 were females (56%) and 100 males (44%). Mucous polypus was present in 11 cases (5%)—in 8 men and in 3 women. Of the 226 cases, 133 received one series of treatments only; of these, 80 did not return, so that the results could not be ascertained. In the remaining 53 cases which were followed up, 41 were free from symptoms, 9 were improved, and in 3 there was no change. Sixty-three cases received two series of treatments. After the first series 38 were free from symptoms or much improved, 19 improved, and 6 showed no change. Of 24 observed after the second treatment, 18 were free from symptoms, 3 improved, and 3 unchanged. In a third group of 22 cases receiving three courses of treatment there was only one in which it had no effect. There were also two other small groups receiving four and five series of treatments respectively. In all these the results were satisfactory. Of the 146 cases followed up, 18 (12%) were insensitive to one or more of the series of treatments; 8 of these reacted favourably to some of the series of treatments, and in 10 (7%) the treatment had no effect.

The author calculates from a survey of the cases that freedom from symptoms, or at least improvement, may be expected in about 85%. The dosage recommended is 150 *r* repeated three times with an interval of one or two days between the treatments. The sinuses and nasal cavity are irradiated with a filter of 0.5 Cu + 1 mm. Al distance 40 cm., with the eyes and eyebrows protected. Decreasing the dose to 100 *r* or 75 *r* did not produce such good results. The author therefore advises 100 or 150 *r* × 3, after a careful survey of the effects of different doses. Neither anosmia, atrophy, nor ozaena followed in any of the cases, and the sense of smell returned in a few. It appears, therefore, that with such small dosage no damage to the mucous membrane need be feared. It is suggested that the good effect is produced by the action of the *x* rays on the blood vessels of the mucous membrane, rendering them insensitive to the antigens. Should this form of treatment be found effective on further trial, it should be a valuable addition to the management of a troublesome condition hitherto difficult to treat.

ERGOTAMINE FOR MIGRAINE

It is now generally known that ergotamine tartrate is effective in treating typical migraine; this is defined as a condition in which there are periodic headaches, usually hemicranial, associated with nausea, vomiting, scotomas, and a family history of similar headaches. The use of ergotamine tartrate for this purpose was introduced by Maier[4] in 1926; it is usually given by subcutaneous or intramuscular injection in a dose of 0.25 mg. or 0.5 mg., not more than 1.0 mg. being administered in 24 hours. If it is given orally in tablets to be allowed to dissolve under the tongue larger doses must be used, since absorption is less complete, and, after an initial dose of 5.0 mg., 2.0 mg. may be taken hourly to a total of 11.0 mg. On the whole it is preferable to inject ergotamine, as there is less likelihood of untoward effects. Von Storch[5] has reviewed 42 accidents described in the literature, of which 21 were gangrene; ergotamine is of course one of the active principles in ergot which have led to gangrenous ergotism. Accidents are likely to arise only when ergotamine is used continuously, and no serious complications have been observed in migraine. The best results are obtained when it is administered early in the attack, and when care is taken to give no more than is needed.

The mechanism of the action of ergotamine is still unknown. It causes a rise of blood pressure and an increased cerebral blood-flow, but other agents which have these effects, such as adrenaline or inhalation of CO_2, do not always relieve headache. Graham and Wolff[6] state that the curative effect is exerted in parallel with a reduction in the amplitude of pulsation in the temporal artery, and is to be attributed to a constriction of the cranial vessels. Recently Horton, Peters, and Blumenthal[7] have tried the effect of a derivative, dihydroergotamine. This is stated to be less toxic than ergotamine and to produce gangrene to a much smaller extent. No experimental details in support of these statements have yet been published, and it is wise to wait for the evidence, since dihydroergotamine is a vasoconstrictor, and like ergotamine produces (in sufficient dose in animals) paralysis of the sympathetic. Nevertheless evidence from 120 patients indicates that this substance is as effective as ergotamine tartrate in the treatment of migraine, 75% of the patients receiving relief. (This is less than the 90% described as getting relief by Lennox and von Storch.[8]) If it is true that dihydroergotamine is less prolonged in action than ergotamine, this property would make it a safer substance to use.

It is interesting to note that in the period of nearly twenty years since ergotamine was used for migraine no one has thought it worth while to investigate the value of ergotoxine. This substance ought to have precisely the same action as ergotamine in migraine, judging from its pharmacological properties.

BIOTIN

Biotin, the most recently discovered member of the vitamin B complex, is a growth factor for many bacteria and moulds and an essential nutrilite for most animals, and possibly man, in whom biotin deficiency has been reported by two groups of observers. Experimental biotin deficiency in animals has been brought on by limiting the biotin intake over long periods; including in the diet raw egg-white, which inactivates the vitamin; and by adding sulphonamide drugs to an adequate diet. The feeding of sulphonamides, particularly sulphaguanidine and succinylsulphathiazole, is one of the most recent methods of inducing vitamin deficiencies in animals. These drugs act by interfering with the bacterial synthesis of vitamins in the intestine, particularly the synthesis of the vitamin B complex and vitamins E and K. Waisman and his colleagues[9] have recently produced chronic biotin deficiency in monkeys by all three methods. This is characterized by a thinning of the fur, a gradual loss of colour of the hair, and in the later stages a heavy, scaly dermatitis covering the whole body but most conspicuous on the face, arms, and legs. The loss of hair is also affected by hormonal influences, as indicated by the slower regrowth of fur in menstruating and adolescent females. Twenty µg. of biotin daily was sufficient to prevent the deficiency symptoms. The biotin deficiency from feeding egg-white was similar to that from adding sulphonamides to the diet. The prothrombin time was not appreciably affected—a finding in contrast to the increased prothrombin time found in rats given sulphaguanidine or succinylsulphathiazole with their food.[10] Biotin deficiency in man, caused by administering large quantities of egg-white, has been reported by Sydenstricker and his co-workers.[11] They observed a greyish pallor of the skin, anaemia, atrophy of the lingual papillae, and increasing dryness of the skin, which progressed to a maculo-squamous dermatitis of the neck, hands, arms, and legs. A decreased excretion of biotin was observed after seven weeks on the egg-white diet.

Experiments have recently been made on the vitamin activity of biotin isomers and analogues. Biotin is a *d*-compound. The *l*- and *dl*- (or racemic) compounds are active only when tested on bacteria in very large quantities,[12] although when assayed on rats maintained on a ration containing egg-white *dl*-biotin is stated to be half as active as biotin.[13] When assayed on chicks *l*- and *dl*-biotin show no activity at all.[14] It is indeed remarkable how slight changes in the chemical constitution, or even the optical activity, of a vitamin can profoundly affect its physiological activity. This is seen not only in the case of biotin but also with other B vitamins. Slight modification of the chemical constitution of pantothenic acid,[15] vitamin B_1,[16] and riboflavin,[17] for example, results in products which are not only devoid of any vitamin-like action, but when fed to animals actually produce deficiency symptoms identical with those produced by lack of the vitamin they resemble chemically.

A JOURNAL OUT OF BONDAGE

Before the war the journal of the Norwegian Medical Association—*Tidsskrift for den Norske Laegeforening*—was a fortnightly publication in a faded brick-red cover of small size but with quite meaty contents. Soon after the German invasion a handful of quisling doctors took it over. Dr. J. H. Berner, its editor for many years, was dismissed and locked up. The colour and format of the journal remained, but its contents became a quaint parody of the past. Its cover was the cover of medical science, but its voice was the voice of Terboven and Quisling. The writers of original articles would no longer write for the *Tidsskrift*. So the decree went forth that no Norwegian doctor could publish his observations elsewhere without the permission of the reigning authorities. Whereat original articles remained locked up at home, awaiting better times. So the captive journal came to consist mainly of abstracts (from German publications, of course) and of editorial notices drafted alternately in truculent tones and come-home-to-mother sobs. Now the old staff of the journal is back in place, and to celebrate its liberation it has changed its colour and format. The upper third of the cover is a greyish-green; the lower two-thirds are white. The format has grown, and it is now a few centimetres larger in both directions than the *British Medical Journal*. The contents are a judicious blend of home and foreign medicine—altogether a very agreeable set-up. We send greetings to an old friend in new guise.

The Central Medical War Committee is informed that Royal Air Force medical officers in age-service groups 19 and 20 will be released during November. These groups have been brought forward from December. Groups 21 and 22 will be released during December, and Group 23 during January, 1946.

Sir John Boyd Orr, M.D., F.R.S., has been elected Director-General of the Food and Agriculture Organization of the United Nations, now in conference at Quebec.

TUBERCULOSIS AMONG PRISONERS OF WAR IN GERMANY

BY

A. L. COCHRANE, M.B., B.Ch.
Capt., R.A.M.C.

During my four years as a prisoner I worked in a transit camp, a "Krankein-revier" (camp reception station), doing sick parades for the surrounding camps, a general hospital, and the special hospital for cases of tuberculosis. All these hospitals were mixed—i.e., contained prisoners of war of more than one nation—and in all of them I looked after the Tb.s, so that I was able to get some idea of the general picture of tuberculosis among these prisoners in Germany.

General Considerations

The living conditions of P.O.W. workers in Germany varied. They depended on the area of Germany, the type of work, the nationality of the prisoner, and the character of the Kommando Führer. In general the Russians had the worst conditions; all Russian Kommandos that I saw were overcrowded, badly ventilated, and dark, but I was not allowed to see many. The British and Americans, in general, had the best conditions, but even they were usually overcrowded.

Diet also differed: the German rations varied according to the type of work done, and also, to some extent, according to local supplies and nationality (Russians until the summer of 1944 received lower rations than others doing the same type of work). It is always difficult to determine from hearsay how much someone else is eating, so I am giving here only the diets I myself received. Doctors, orderlies, and patients were classed as "Normal-Arbeiters" along with the non-manual workers, and their diet in the various places where I worked was as follows:

1941: Transit camp	Approx. 1,000 cals. p.d.	for 6 months
1942–3: General hospital	" 1,600 " "	" 2 years
1944: Special hospital for Tb.s ..	" 1,800 " "	" 1 year
1945: "Revier"	" 1,300 " "	" 5 months

With such low basic diets, Red Cross food parcels became very important. The Americans and British were fortunate in usually having a parcel a week, which added about 1,500 calories a day to their diet. The French until 1944 also received parcels regularly, but Serbs, Poles, and Italians received very little and the Russians nothing at all.

The Germans apparently realized that such conditions were likely to produce a high incidence of tuberculosis, so in 1942 they instituted routine mass radiography. I was told verbally by a German that their reason for doing this was not humanitarian, but their fear that tuberculous P.O.W.s would infect German civilian workers. This view of the matter was supported by the German refusal to *x*-ray officers at Oflag (who had little contact with the civilians) until long after they had *x*-rayed all the working camps in the same area, and also by the lack of treatment and facilities given when the diagnosis had been made. The *x*-raying was carried out efficiently and quickly by mobile units, usually staffed by women. No figures are available as to the proportion of the P.O.W.s who were *x*-rayed. It was probably about 60%; but it is only fair to say that in some areas some P.O.W.s had two mass radiographs in five years. The diagnosing of the films was in general poor. There were also cases—far too many—where the films were correctly diagnosed but no action was taken, and the P.O.W. was left for another year spreading bacilli until he was diagnosed clinically.

Some idea of the poorness of the evaluation of the films can be obtained from the figures from Elsterhorst. During 1944 I analysed 68 consecutive sputum-positive cases admitted into Elsterhorst under my care. Of these, 19 had been diagnosed by means of radiography; the remaining 49 were diagnosed by clinical means. Of the latter, 13 had had routine skiagrams and been "missed," or were found positive but no action had been taken. It was very easy to check up on these cases, as the small skiagrams arrived with the patients with the diagnosis attached—*x*-ray positive or negative. It is important that the double danger of these "missed" cases should be realized. It is psychologically very difficult for an M.O. to make a diagnosis of tuberculosis when he knows that the patient has recently been radiographed and been declared negative. Another danger, due to the lack of explanation given by the Germans, arising from the mass radiography was the "Tb. neurosis" which spread rapidly among the prisoners.

The "Revier" and the Sick Parades

When doing such jobs the P.O.W. medical officer was responsible for the sick parades for all the surrounding working Kommandos and had a 50-bed hospital at his disposal. I did this work at Wittenberg for the last five months of the war, and it is on that area that most of these remarks are based. Some idea of the incidence of tuberculosis is given by the following figures for the French and Russian P.O.W.s in this area.

Population.—There were in 1943 1,000 French and 1,200 Russians. The number of French remained remarkably constant; the number of Russians fell to 1,000 in 1945. All these P.O.W.s were mass *x*-rayed in 1942 and the early part of 1943. All those who were found positive were removed to hospital. The figures thus give the incidence of pulmonary tuberculosis in a population from which practically all *x*-ray-positive men had been removed by the spring of 1943.

Procedure.—Suspects were discovered by the British M.O.s on sick parades, and a portion of these suspects were screened by a German M.O., who decided, rather arbitrarily, whether they were to be considered as cases of active tuberculosis or not. Only those accepted by the German M.O. are included in these figures, which can therefore be considered as minimal.

Figures.—A double check was possible through the "screening" reports and the admission and discharge book. The figures were also checked by my Dutch secretary. Those for 1945 are given for the first three months only.

	French (1,200)	Russian (1,200–1,000)	British (250)
1943, July–Dec.	0	6	0
1944, Jan.–June	1	14	0
" July–Dec.	1	31	0
1945, Jan.–April (3 months) ..	4	11	0

Comment on the high incidence of tuberculosis among the Russians is almost superfluous. Reference has already been made to the conditions under which they lived and the diet they received. In Wittenberg it was striking that there were scarcely any big Russians left in 1945: lower metabolic demands had a very definite survival value. The raised incidence among the French in 1945 was doubtless a reflection of the absence of parcels from France after 1944.

Another interesting feature of Wittenberg medical life in 1945 was the appearance of 350 Danish policemen. These men, who were all of outstandingly good physique, had been made prisoners of war in Sept., 1944. They spent three months in a concentration camp and then came to a working party in Wittenberg. In the concentration camp the living and working conditions were fearful, but their diet was adequate, as they got excellent food parcels from Denmark weekly. They stayed only two months at Wittenberg, but I diagnosed seven cases of open active tuberculosis and four of pleurisy with effusion. In this instance it seemed that living conditions, other than diet, were mainly responsible.

On these sick parades the early diagnosis of tuberculosis presented quite unusual difficulties. They lasted from 8 a.m. until frequently to 2 p.m., and after 11 o'clock my efficiency deteriorated, particularly as we were at the time without parcels and on the 1,200-cal. German diet. With me latterly was a German sergeant, trying to get me on a sabotage charge, so the atmosphere was not restful!

Then there were the languages—Russian, Serbian, French, Dutch, Indian, Danish, Slovakian, Italian, Polish—to say nothing of the German I had to talk to the sergeant. I learnt to take a decent tuberculosis history in Russian, French, Serbian, Dutch, Italian, and German, and then to my dismay found I was no further on. All the patients were tired and wanted a rest; all of them wanted to do as little work as possible for Nazi Germany. I was a new doctor, and it was unreasonable to expect them to trust me at once; so I found that all Serbs and Indians said they suffered from haemoptysis, and all Serbs gave gruesome family histories. All Frenchmen seemed to have had pleurisies (they muddled up "pleurite" and "pleurisie").

Serbs and Indians all gave good histories of night sweats, and nearly everyone coughed and really had lost weight. The Russians were interesting; they rarely admitted tuberculous symptoms. I discovered the reason for this later; they were terrified of being sent to the special hospital for Russian cases because they thought everyone died there, and, so far as I could make out, they were quite right. The advanced Russian cases, while waiting at Wittenberg "Revier" for transport to "Zeitheim," actually escaped to avoid going there.

When the histories proved so fallacious, I tried doing a larger number of B.S.R.s. Here too I found new difficulties. The high incidence of skin disease and slight hypoproteinaemic oedema made the B.S.R. more difficult than usual to interpret.

Having collected one's suspects, the next step was to get them *x*-rayed or screened. In many areas this was very difficult indeed, the Germans being most obstructive. At Wittenberg I was lucky in that I finally persuaded the German M.O. to let me screen 10 to 12 cases with him each week. In some other areas a positive sputum in addition was demanded before cases could be sent to hospital, and the Germans tended to argue that one negative sputum was proof that the case was inactive. This was particularly dangerous, as the German laboratories were very slack about P.O.W. sputa. There were also other difficulties. I once sent three sputa from one case to three different laboratories. Each one was said to have been destroyed by bombing. German M.O.s claimed that if they heard nothing abnormal clinically there could be nothing wrong with the patient.

The General Hospital (Reserv Lazarett)

My experience of this comes from looking after Serbian, French, and British tuberculosis cases at a Reserv Lazarett for two years. Here the problems of the early diagnosis of tuberculosis were slightly easier, as one could do one's own sputa and there was more leisure for multilingual activities; but the German doctor would never accept the sputum results done by prisoners of war—they had to be sent to a German laboratory; and I had for a time to take histories in Serbian and write them in German!

As regards screening, I had the same arrangements at Wittenberg. I screened about 6 suspects a week with a German civilian doctor—in this case a woman. At one period a German M.O. made a written protest against my being allowed in a dark-room with a German Frau—it was apparently a risk to the purity of German blood (!); but after a short interruption the screenings continued.

The great problem at the Reserv Lazarett was that of treatment. This should never have been a problem at all, as the cases should have been evacuated to the special hospitals; but in practice they stayed three to six months. There were many reasons for this: (*a*) Owing to lack of repatriation the special hospitals got overfilled. (*b*) The Germans made absurd transport rules. One was that you must have six of one nationality before you could have a transport. We then had relatively few British, and by the time we had five cases of tuberculosis the old ones started dying. (*c*) Sheer obstructionism: on many occasions when the Chef-arzt stated that he had asked for transport we found through our spy in the office that he had not. (*d*) In some general hospitals there was a regrettable lack of information about even the facilities at the special hospital, and cases were often kept for over a year, and cases of A.P.T. with adhesions were abandoned before being sent there. This lack of information was entirely due to the inefficiency of the Germans.

The basic diet, as already stated, was about 1,600 calories in these hospitals, and of this the tuberculosis patients found a large proportion uneatable. Frequent requests were made for extra food, but these were always refused until early in 1943, when a little milk was allowed, and later occasional eggs and white bread; but the available diet from the Germans was never more than 1,900 calories a day. The British patients did not suffer, as a satisfactory diet could always be made up from Red Cross food parcels and invalid comfort parcels; but the problem was very difficult for a British doctor looking after tuberculous Serb and French patients. (There were no Russians in this particular hospital.) We were unable to get any instructions from London, and there was unfortunately some feeling against giving British food to other nationalities. I think, however, that all British M.O.s did give as much food as could be spared; I certainly did, and the results were well worth it.

Active treatment was very difficult there—the German doctor had never heard of it. Finally in 1943 I got an A.P.T. machine, but was then forbidden to use it, because the German doctor believed that A.P.T. cases could not travel in trains and thus could not be evacuated. The patients at Hospital 1251 did get complete rest, but often under difficulty. One reason for this was the shortage of orderlies. At one stage we had seven orderlies for 120 patients, of whom 20 were cases of tuberculosis. These orderlies had to fetch food and run the laboratory in addition to their ordinary day and night duty. They, too, were afraid of treating the disease, and some became very neurotic.

When working at Elsterhorst one was able to get some idea of the amount of rest tuberculous patients were obtaining at the various other general hospitals in Germany. On the whole the information was very depressing. Only a few of the open active cases were at complete rest; some had even been encouraged to do physical jerks, many had been for walks, many did their own cooking. There seemed unfortunately to be a widespread belief that if a patient was afebrile he could get up and walk, however big his cavity. That was found not only among German but also among Allied and British doctors.

It is worth while mentioning the cemetery at Hospital 1251. The P.O.W. section there served both a surgical and a medical hospital, but 80% of the graves were filled with victims of tuberculosis. This, I think, gives some idea of the prevalence of the disease in imprisonment.

The type of transport between general hospitals and the special tuberculosis hospitals was very bad. Originally patients travelled in unheated cattle-trucks without even straw and orderlies. After persistent complaint we evolved step by step—getting first straw, then orderlies, then heat, and finally reserved third-class compartments. Later we degenerated again. I remember in 1944 some tuberculous Canadians arriving at Elsterhorst. They included a case of tuberculous meningitis, a spontaneous A.P.T. with empyema, and a case of tuberculosis with diabetes; they had travelled three days in an unheated cattle-truck, with no orderlies, little food, and no insulin. In spite of innumerable complaints travelling facilities got worse and worse as the end of the war approached.

Special Hospitals

1. "Königswartha" was originally a hospital for tuberculous French P.O.W.s. The first English cases arrived there after the fiasco of the Rouen evacuation. Originally a blind asylum, it had limited accommodation, poor cooking facilities, pleasant gardens, and bad sanitation. At that time the repatriation prospects were *nil*, and inevitably the hospital developed into a pleasant place to die in rather than a serious hospital, although much good work was done there.

2. Elsterhorst became the chief hospital for tuberculosis in 1943 after numerous complaints from the British about the overcrowding at Königswartha. This was a modern German standard hutted hospital. The cooking facilities, the sanitation, and the wards were good, but unfortunately it was situated in the middle of a sandy plain, and there was a severe water shortage and no shade in summer. The hospital was six kilometres from the nearest station, and inevitably a large number of advanced bilateral cases were forced to walk that distance carrying their kit. There was, too, the inevitable wire round the hospital. Security measures were not too severe until 1944, when a stringent curfew at 9 p.m. was introduced, and doctors and orderlies were not allowed to move from one barrack to another after that time without a guard. As it took five or ten minutes to get a guard this made emergencies at night very dangerous. Searches also started at this time; it was an odd sight to see soldiers of the Third Reich search men with advanced tuberculosis in bed and remove excess food—in case they escaped! Actually the soldiers were ashamed; they did the work gently, and it cleaned the lockers. There was another odd sight when a big convoy of tuberculous patients arrived from Lamsdorf. The truck drove into the hospital and was then surrounded by soldiers with fixed bayonets to prevent doctors getting near until the men had been searched. I was finally thrown out of the hospital when I stated that it was

ein Skandal im Lande von Robert Koch" when the Chefarzt ordered me to put a febrile bilateral A.P.T. case with fluid on to an open truck with snow falling and the temperature well below zero.

Dietetically the Germans were not over-generous; they provided about 2,000 calories a day, of which ill patients could manage to eat only part. However, with the help of food parcels, invalid comfort parcels, and a black market, the patients were probably the best fed in Europe. They suffered only from a lack of fresh vegetables and a somewhat monotonous menu. It was very striking that, there in the heart of Germany in the middle of the war, three-fifths of the food eaten should come from the Allies.

All the usual methods of collapse therapy were employed in the hospital, except Monaldi's, and on the whole the patients rested well. It is difficult to present any picture of the type of treatment given in a hospital without going into great detail, but the following figures from a series of consecutive positive cases in 1944, when the hospital was at its best, may help:

Positive cases with at least 3 months' stay in hospital	44
No. of A.P.T.s attempted	39
„ „ successful	31

Of the A.P.T.s 2 were made bilateral and 5 were abandoned. Of the 13 failed or abandoned A.P.T. cases 7 later had a phrenic avulsion and one in addition a rather unsuccessful pneumoperitoneum. Of the successful A.P.T.s which were not abandoned (26) 20 had thoracoscopies with or without adhesion-section. Of all these, one died at Elsterhorst and 24 became negative before leaving, after an average of 3.3 months in hospital—i.e., 54.4%. The latter figure should not be taken too seriously—the total is too small and our facilities for detecting bacilli were not very advanced; but all the cases which I have so far checked up on in England have remained negative, and several more have become negative.

The hospital was originally completely international; there were Australians, New Zealanders, Canadians, South Africans, Cypriots, Indians, Americans, French, Poles, Serbs, Dutch, Norwegians, Spaniards, Italians, negroes, to say nothing of the English, the Welsh, the Irish, the Scots, and the Channel Islanders, among the patients; and the Russians helped with the work of the hospital. On the whole they lived together in peace—chiefly, perhaps, because they all received British Red Cross parcels !

It would be wrong to mention Elsterhorst without naming Lieut.-Col. Le Souef, A.A.M.C., and Major Wallis, R.A.M.C. Everyone at Elsterhorst owes them a great debt of gratitude, and I am sure the vast majority share my admiration and affection for them both.

Nova et Vetera

THE HISTORY OF SYPHILIS

In the month of February, 1495, Charles VIII of France arrived with his mercenaries before the city of Naples. The city fell almost without opposition, and there followed in the armies of both sides, and in civilians, an outbreak of a virulent disease which had not been long known in Europe. The results of this mixing of mercenaries and civilians were tragic, and when Charles disbanded his army at Lyons seven months later the disease was already causing many deaths in addition to horrible features and painful symptoms. Ruy Dias de Isla called it the *Morbo Serpentino*—hideous, dangerous, and terrible as the serpent itself. Throughout much of the following century the disease was epidemic, and presented all the characters of any serious epidemic disease which attacks an unprotected population. Thereafter the people of Europe developed some degree of immunity, so that the disease now became more remarkable for its chronic manifestations. In 1530 Fracastorius, the greatest of the early epidemiologists and the wielder of a Latin measure almost as stately as that moulded by the swan of Mantua, wrote a poem in which he named the disease "syphilis." Nearly two centuries later the name found its way into medical writings. In the four and a half centuries since it first attracted attention it has been the subject of a vast literature. There have been many histories of syphilis, but there is even now no agreement on certain moot points. In a recent Vicary Lecture at the Royal College of Surgeons Mr. J. Johnston Abraham[1] tackled the subject again, and his contribution will be read with great interest even by those who are familiar with the subject.

There will always be those who regard the first origin of syphilis in Europe as a purely academic question. Mr. Johnston Abraham does not commit himself on this point, but it is perhaps not difficult to see where his sympathies lie. Although he says that syphilis was *apparently* an unknown disease in Europe in 1495, in his discussion of the Columban origin he cites writers such as de Isla, Fernandez de Oviedo, and las Casas, who were impressed by the violence of the outbreak—unlike anything they had previously known. There is an important school which believes that syphilis had been known in Europe since the earliest times. Sudhoff, for example, considered that mercury was being used from at least the twelfth century for certain skin conditions which were probably syphilitic. The matter will probably never be settled. Apart from the dramatic events of the fifteenth and sixteenth centuries, the author concentrates in this lecture mainly on methods of treatment and on the monist and dualist theories of the disease. The condition which we now know as gonorrhoea had been recognized for centuries. John Arderne mentioned "chaude pisse," as it was then termed. Paracelsus lent his great weight to the theory—advanced shortly before his time—that syphilis and gonorrhoea were one and the same disease. The unfortunate experiment which John Hunter performed on himself in 1767 seemed to prove that the monists were right. Although Benjamin Bell published evidence to the contrary in 1793, and Richard Carmichael taught in 1814 that they were different diseases, it was not until the publication of the painstaking experiments of Ricord in 1838 that the dualist theory became widely accepted. There is evidence—for example, the statement of Gaspar Torella—that mercury was used in the treatment of syphilis before the end of the fifteenth century. As a result partly of the unscrupulous action of quacks the orthodox profession was forced to give larger and larger doses, until a course of mercurials was an abominable ordeal for the unfortunate patient. China root and sarsaparilla enjoyed a brief hour on the stage, but guaiac, first introduced in 1517, had a longer run. Wallace of Dublin used potassium iodide in the eighteen-thirties, and Auzias-Turenne in 1850 recommended inoculation of the patient with pus from a soft sore. He continued to advocate his method of "syphilization" for a period of twenty-eight years! The modern armamentarium, based on the work of Schaudinn and Ehrlich, is outside the scope of the lecture.

There are few diseases whose history is so difficult to write concisely and fairly as that of syphilis. Mr. Johnston Abraham has succeeded in a difficult task in this admirable and well-illustrated lecture. Many will also be grateful to him for giving the true derivation of the term "Lock Hospital"—from the French *les loques* (rags), with which the lazars wiped their sores before they entered the lazar houses in the days when these institutions, used less and less for their original purpose, were turned over to the victims of syphilis, the new epidemic disease.

E. A. U.

VARRIER-JONES MEMORIAL LECTURE

As a memorial to the late Sir Pendrill Varrier-Jones, the founder and first medical director of Papworth Village Settlement for the Tuberculous, near Cambridge, an annual memorial lecture has been instituted. The first was given by Wing Commander, now Air Commodore, R. R. Trail, who has succeeded Sir Pendrill as medical director of Papworth and its associated centre at Enham, and the second by Sir Arthur MacNalty, who was Chief Medical Officer of the Ministry of Health from 1935 to 1941. The third lecture of the series is to be given in London at the Hospital for Sick Children, Great Ormond Street, on Wednesday next, Nov. 14, by Dr. Alan Moncrieff. His subject is "Tuberculosis in Childhood," and in it he will make special reference to the exhaustive survey of the children of Papworth, prepared from Papworth records extending over more than 25 years by Dr. E. M. Brieger. This survey, published under the title *The Papworth Families*, establishes the success of Papworth in protecting Papworth-born children against tuberculosis, and demonstrates anew that the children of the tuberculous need not contract the disease and indeed will not do so if the family's domestic conditions permit medical advice to be carried out.

BRITISH ORTHOPAEDIC ASSOCIATION

ANNUAL DINNER

The British Orthopaedic Association held its Annual Meeting Dinner at Lincoln's Inn on Oct. 26, when some 200 members and guests were present. Mr. St. J. D. Buxton presided. Proposing the health of the B.O.A., Dr. Charles Hill, Secretary of the B.M.A., referred to the contributions which the Association had made in recent years to the profession's planning of medical services and, in particular, of accident services. He added that the B.M.A.'s Report on Fractures was the starting-point of much progress. Referring to present problems and to the new situation with which the profession was confronted, he said that the profession had little to fear provided that in its proposals it adhered to what was in the public interest. The unity of the profession in all its branches was essential at the present time.

In response, Mr. Buxton said that it was in 1918–19 that, thanks largely to Sir Robert Jones, the position of orthopaedic surgery in relation to the Services had been well established. By 1939 much had been forgotten, and orthopaedic work had to be organized by individuals. It was, however, true that the education of young surgeons and would-be surgeons in orthopaedics had developed, and should be developed further, in co-operation with other surgical specialties. Prof. H. J. Seddon gave an entertaining account of the guests, among whom were Lord Moran, Sir Alfred Webb-Johnson, and Sir Wilson Jameson. Sir Alfred, he said, was now breaking down the barriers between specialist and general surgeons, and there was now no antagonism "between the great realm of orthopaedic surgery and the little rump known as general surgery." Replying for the guests, Sir Wilson Jameson, Chief Medical Officer to the Ministry of Health, spoke of the need for interchange between different departments of medical work, and referred to the way in which orthopaedic surgeons had grown accustomed to co-operation with central and local government. He hoped that this example would be widely followed, so that the National Health Service could be built up in the best possible way. The President's health was drunk with musical honours on the proposal of Mr. George Perkins, President-Elect.

HEBERDEN SOCIETY

At the dinner of the Heberden Society last week, Dr. C. W. Buckley, in his presidential address, said that the Society was now entering a new chapter in its history—a chapter which he hoped would be associated with important advances in the study of the common diseases grouped under the term "rheumatic." "They have appeared frequently to be regarded as unworthy of the attention of professors of medicine interested mainly in higher things. . . ." Among men whose names were associated with rheumatism were the Heberdens, father and son, and the Garrods, father and son again. To Archibald Garrod belonged much of the credit for advancing the study of chronic rheumatism. The appointment by the B.M.A. of a committee in 1931 to report on chronic rheumatic disease was an important indication of awakening interest. Three years after this the Royal College of Physicians appointed a committee with a similar object, and the publication of its *Reports* was a forerunner of the *Annals of the Rheumatic Diseases* (now published quarterly by the B.M.A.). Another landmark was the formation of the Empire Rheumatism Council, which owed its inception largely to the vision and energy of Lord Horder. In addition to its propaganda work, the Council had done much to direct and subsidize research. When the Empire Rheumatism Council was being formed the medical staff of the Red Cross Clinic formed with others a society for the discussion of the clinical and pathological aspects of chronic rheumatic disease, and adopted the name of Heberden. Notable among the researches carried out by members of this society had been the work of Copeman and his colleagues on fibrositis. The revival of the Heberden Society had been marked by its affiliation with the Empire Rheumatism Council, and its proceedings would be published in the *Annals of the Rheumatic Diseases.*

General practice, Dr. Buckley went on to say, provided an unrivalled field for clinical observation on hereditary, family, social, occupational, climatic, and meteorological influences, and he hoped that the Society would encourage practitioners to study these problems. He questioned whether any group of diseases had suffered more from methods of treatment advised without any consideration of the underlying pathology. There were few cases in which properly directed physiotherapy was not a most essential part of the treatment of chronic rheumatism; but a wide acquaintance with physical methods did not make a specialist in rheumatic diseases. The primary object of the Heberden Society was the study of rheumatic diseases from the standpoint of clinical medicine and pathology. At the moment the number of members was limited to 100.

After the presidential address, the toast of the guests was proposed by Brigadier F. D. Howitt, who extended a special welcome to Colonel C. W. B. Littlejohn and Colonel J. H. Anderson of the Australian Army Medical Corps, to Sir Frank Fox, secretary of the Empire Rheumatism Council, and to Mr. Tom Williams, the Minister of Agriculture and Fisheries. Mr. Tom Williams and Colonel Littlejohn then replied on behalf of the guests.

RESEARCH ON AGEING

In 1939 a Club for Research on Ageing was established. This actually represents a team of medical and scientific research workers for study and research on ageing, and is not a society in the ordinary sense of the word. There are branches of the club in Great Britain, the United States of America, France, Argentina, and also members in Denmark and Switzerland. A branch in Sweden is in process of formation.

The governing bodies of the branches of the club consist of the following members of the British branch—Prof. G. R. Cameron, Prof. E. C. Dodds, F.R.S., Prof. Sir Robert Robinson, F.R.S. (chairman), Lady Robinson (hon. treasurer), Prof. M. J. Stewart, Dr. V. Korenchevsky (hon. secretary); of the branch in U.S.A.—Prof. W. de B. MacNider (chairman); Dr. E. J. Stieglitz (secretary), and of the executive committee—Prof. E. V. Cowdry (chairman), Prof. A. B. Hastings, and Prof. H. S. Simms; of the group in Argentina—Prof. B. H. Houssay (chairman) and Dr. E. E. Krapf (hon. secretary); of the French branch—Prof. R. Courrier (hon. secretary).

The number of members is limited; there are only 75 at present, and only those scientific and medical research workers are invited to join the club who are engaged in or direct research on ageing, or promise to do so, and who belong to qualified research laboratories or hospitals. Unfortunately the war has badly handicapped the activities of the club, especially in Great Britain and Europe.

Lord Nuffield, and later the Nuffield Foundation, generously supported a scheme of clinical research work carried out in co-operation with the London County Council at one of the Council's hospitals (Tooting Bec Hospital). The results of these clinical trials are now being examined. At the end of 1944 Lord Nuffield also made a donation of £3,000 in order to establish an experimental laboratory for research on ageing, the Gerontological Research Unit, at present housed at the Departments of Zoology and Physiology of Oxford University (head of the unit—Dr. V. Korenchevsky). Thus the foresight and generosity of Lord Nuffield have made actual research work possible in this country.

In the U.S.A. the branch of the club has had annual conferences, at which the schemes of research were discussed and planned; a museum of senile tissues has been established; clinical research on the effects of vitamins on old persons was started at the Elgin Hospital; and finally a *Journal of Gerontology* has been started. For the latter purpose a special "Gerontological Society Inc." was formed, consisting of the members of the American branch of the club. The editor-in-chief of the journal is Dr. Robert A. Moore, professor of pathology of Washington University. The committee on publications consists of Professors Roy G. Hoskins, M.D. (chairman), and W. de B. MacNider, M.D., and Drs. P. Bronson, L. K. Frank, and E. J. Stieglitz. The correspondent for Great Britain is Dr. V. Korenchevsky.

The journal will be published quarterly, the first number appearing at the beginning of 1946. Besides original papers, it will contain reviews and abstracts on gerontology. It will also contain a special section, "Browsing through the Ages," devoted to a scholarly treatment of some topic from the field of art or literature related to ageing and the aged. The address of the *Journal of Gerontology* is 507, South Euclid, St. Louis, U.S.A.

D. Solomons (*J. roy. nav. med. Serv.*, 1941, **31**, 178) in the course of a year saw 19 cases of infective mononucleosis, in 8 of which meningism was the outstanding feature; in 4 a rise in the pressure of the cerebrospinal fluid was the only abnormality. Nothing abnormal was found in the fluid of any of the other cases.

MEDICAL PRISONERS IN SINGAPORE

The following letter from Dr. R. E. Anderson, honorary secretary of the Malaya Branch, has just been received by the Secretary of the B.M.A., and in view of the interest and especially of the concern we all feel in the fate of our colleagues in the Far East we publish it in full.

c/o The Bank of New South Wales,
Melbourne, Victoria,
Australia.
October 18, 1945.

Dear Dr. Hill,

I am writing to you following on my arrival in Australia after release from internment in Singapore to enclose lists of the medical profession who were civilian internees or military prisoners in Singapore. I have marked with an "M" all those who were on our list as members of the Malaya Branch at the time of the fall of Singapore.

I regret to inform you that four civilian doctors died during their internment: Dr. C. A. Stanley, Dr. J. H. Bowyer, Dr. E. S. Lawrie, and Dr. H. J. Lawson; all of them were members of the Malaya Branch. Dr. Norris was killed while working at Kandang Kerbau Hospital shortly before the capitulation; he was also a member. As far as I know none of the Malayan doctors who were in the prisoner-of-war camps died, but it is regretted that Dr. D. F. Irvine and Dr. W. R. Logan, both members, and Dr. Donaldson (of the Malacca Medical Board) were killed in the fighting which preceded capitulation. Drs. Stanley and Bowyer died as a direct result of the cruelties of the Japanese Military Police, the former dying while in their hands and the latter was returned to us *in extremis*. Of those whose names appear on the lists a few are invalids and received all care and attention on release, but I am happy to say that the majority of us are reasonably well and have all been repatriated.

As you have doubtless heard, conditions in Japanese prisoner-of-war and internment camps left much to be desired; overcrowding was the rule and semi-starvation, especially in the past year, was common. I am not in a position to give information regarding the prisoner-of-war camps, and what follows applies to civilian internees. We were housed for the first two years of our internment in the Changi Prison, Singapore, over 3,000 persons being housed in a criminal prison designed for 600 delinquents. For the last year and a half we were housed in the Sime Road Camp, former R.A.F. headquarters which had been burnt out and rebuilt. While conditions on the whole were better in the second camp the reduction of rations and lack of suitable food and drugs brought many to the verge of grave deficiency disease. All admit that had it not been for the efforts of our profession and the expedients adopted such diseases would have taken a heavier toll, and excellent work was done by our medical staff, despite the lack of essential foods and drugs, to maintain a reasonable standard of health.

The chief medical officer of the camp was first of all Dr. J. H. Bowyer (since dead), and then Dr. J. W. Winchester, our president-elect for 1942. The chief health officer was Dr. D. W. G. Faris, and both these men were assisted by medical and health officers from the Malayan Medical Service and from private practice. Mention must also be made of a committee to which all nutritional questions were referred; it consisted of Dr. G. V. Allen (Editor of the *Journal*), Dr. W. R. Duff, and Dr. R. G. Scott MacGregor. These men by their sound advice and unerring judgment have been instrumental in saving much serious illness. But to mention all by name would be invidious; there were too many of us to permit all of us to function as doctors, and many of us (including myself) played the part of the ordinary internee and worked on general fatigues, which included wood-cutting, gardening, kitchen work, and latterly work of a military nature forced upon us by the Japanese. But I must not omit to mention the good work done by the women doctors, Mesdames Hopkins, Smallwood, Worth, Robinson, and Misses Williams and Elliot, who, with the assistance of sisters and nurses from the Malayan nursing service, ran the hospital for female internees with conspicuous success.

The conditions and medical arrangements were of the worst; for some time we were permitted to send patients to a civil hospital for treatment, but latterly patients were not allowed to leave the camp. The supplies of drugs and dressings were extremely limited and the Japanese medical officer of negative assistance; in fact the impression gained from the few Japanese medical officers we saw was that they were not interested. I believe Dr. Ando, a locally trained Japanese, did what he could, as might be expected from a member of our Association. The supplies we received from the Red Cross were a godsend, though much of the better stuff did not reach us. I am not in a position here to discuss our hospital records, but I may mention that apart from dysentery, malaria, and tropical typhus, we were singularly free from communicable disease. Deficiency diseases and tropical ulcers were our greatest concern.

We were unfortunately unable after the first year or so to hold professional meetings, as these were prohibited by the Japanese along with all other meetings, although when such were allowed we held them under the auspices of the Association. Regarding the Association, I had no time to write you before capitulation; as you can imagine my hands were too full. I am afraid that my records are lost, and while I made an effort to send them to Singapore (you will remember my office was in Ipoh) they did not arrive. Until I am able to make further inquiries I must presume them to be lost. After the Japanese surrender I was able to contact Dr. Lee Choo Neo, our Branch Treasurer, and she was able to tell me that some of her records have been saved, since she was not interned. She believes that what cash assets we had will be safe, as the bulk of them were held by the Post Office Savings Bank.

As to the future of the Branch, which at the moment is in suspense, I can only make a rough forecast. At present Malaya is being run by a military administration and the medical men in this administration are all in uniform. It will, therefore, be possible for them to be military members. But our many Asiatic members are still not catered for, and I can see little hope for them until Malaya returns to more normal conditions. When, however, such conditions prevail and the Malayan Medical Service takes over again from the military administration and private practitioners return to their practices I am confident that the Malaya Branch will resume its activities with renewed vigour. I am concerned, however, about our many Asiatic members, whose names will be found in the supplement to the *Journal of the Malaya Branch* of the British Medical Association for June, 1941. They are anxious to receive journals, I know. Perhaps if you communicated with our treasurer, Dr. Lee Choo Neo, at the Lee Dispensary, Bras Basah Road, Singapore, she might be able to contact those who wish to continue membership, and until further arrangements can be made keep you in touch with them. I am unlikely to return to Malaya for at least six months, if not longer, so I regret that until I do I can be of little assistance. While in Australia my address will be c/o The Bank of New South Wales, Melbourne, and I will keep you informed of any change.

Our president-elect, Dr. J. W. Winchester, is at present in Australia; when I write you again I shall give you his address. Dr. W. H. Brodie (Municipal Health Officer, Penang) left Malaya on leave before hostilities began, and I believe he went to England. He was our president, and I am sure will have contacted you if it were possible. You will doubtless have visits or correspondence from many of our members who are now in England or on their way there, and if it is possible I would be glad to have news of them, though I realize that communications with Australia are slow and erratic. I will probably be in England myself in the spring of 1946, when I hope to call on you. In the meantime, I have seen Dr. Dickson, medical secretary of the Victorian Branch, who has offered me the hospitality of his branch and has kindly offered me the service of his clerical staff for any correspondence with you.

In closing I would like to say that it was with great regret that I heard on my release of the death of Dr. G. C. Anderson, with whom I had corresponded in the past. You naturally have my permission to make public all or any part of this letter in the *Journal* should you consider it to be of general interest.

Yours sincerely,
R. E. ANDERSON.

His Majesty's Government has decided that inventions made in Germany since 1938 shall not be allowed to form the basis of valid applications for the grant of patents, or for registration of designs in the United Kingdom, and accordingly such applications will not be accepted by the Comptroller of the Patent Office. Any rights lawfully acquired by non-enemies before Sept. 3, 1939, in inventions for which protection was applied for in Germany in the twelve months preceding that date will be safeguarded.

Reports of Societies

HYPERTENSION

In his presidential address to the Section of Medicine of the Royal Society of Medicine on Oct. 23 Dr. T. Izod Bennett said that he had chosen as his subject a morbid condition which caused approximately 100,000 deaths in this country every year. His choice of hypertension was made because he felt that we were on the eve of discoveries which would give the profession control over this scourge. Progress towards control of a disease was made usually in three stages: an initial stage in which the condition became defined; a stage during which there was a large accumulation of data; and a stage in which the explanation of its occurrence was worked out—in other words, the stages of "What?" "How?" and "Why?"

It was a long time before any definition or understanding of the problem of hypertension was reached. Not until the last years of the nineteenth century was an answer obtained to the question "What?" Then followed the accumulation of a mass of material which in time answered the question "How?" The final question, "Why?" was still unelucidated, but the darkness was not entirely unrelieved. Here he referred to the brilliant experimental work of Goldblatt and his colleagues in the United States, who, a few years ago, published observations showing that when the renal arteries were partially occluded by the placing of clamps severe hypertension was caused in animals. Byrom and Wilson in this country showed in a number of experiments, extraordinary in conception and equally clever in technical achievement, that if one kidney alone was partly occluded by clamps, not only was hypertension produced but the untouched kidney underwent a change analogous to what was seen in hypertension, and if both kidneys were affected and the original clamp on one of the arteries was removed, the other kidney in certain conditions cleared up.

This work had had as one of its results the use by surgeons of unilateral nephrectomy. In a discussion on this subject in the Section of Urology in 1943 the position was usefully summarized by Dickson Wright, who concluded that "the importance of the surgical kidney in hypertension should be written down rather than up." Simultaneously with the work of Goldblatt and his followers was an important series of observations by the more purely chemical school of workers, the name most prominently associated being Page in the U.S.A. These two schools were now united; all the exponents of the Goldblatt school—or most of them—were of opinion that the effects they brought about must ultimately be due to chemical agents from the affected kidney.

As a practical physician Dr. Izod Bennett reminded the meeting that there was yet another substance which must not be overlooked—namely, potassium thiocyanate. Nobody seemed to know how this acted, but there was no doubt at all that in early cases—cases in which actual sclerosis had not yet taken place—brilliant results were occasionally achieved by its oral administration. The substance was uncertain in its action and toxic if given in too high dosage, but with careful control it could be safely used and undoubtedly afforded great relief in many cases. But he did not anticipate that thiocyanate would continue for long; soon a more logical and probably more effective treatment would be forthcoming.

The Ischaemic Kidney

Major Clifford Wilson said that the ischaemic kidney might show no structural damage. Unilateral renal ischaemia would cause persistent hypertension—that was to say, failure of renal excretion and increasing load on the kidney increased by hypertension. Unilateral renal ischaemia set up acute vascular and parenchymal changes in the opposite kidney and other organs, closely resembling the lesions of malignant hypertension and chronic interstitial nephritis. In man prolonged hypertension might persist after removal of the affected kidney. The speaker showed diagrams of the technique of experiments on renal artery constriction in the rat, and photomicrographs of the damage to the kidney tissue. The most important result of this animal experimentation was that hypertension was shown to produce lesions in the kidney which previously had been regarded as inflammatory or nephritic in origin. It also established beyond doubt the fact that malignant hypertension was an entity—there was a variety of essential hypertension which started without any apparent renal damage and later went on to renal destruction.

These observations suggested the possibility of a vicious circle in Bright's disease in which hypertension was maintained at an increasing tempo, with the result that clinically these patients suddenly got worse and went downhill. It had long been recognized that in any patient with chronic kidney disease and with hypertension the terminal histological picture was very similar. This common picture had been called chronic interstitial nephritis, and that was why chronic interstitial nephritis had been so confusing—it did not correspond to any common entity.

On the question of unilateral-renal hypertension in man, there was naturally a good deal of excitement when many cases were reported in which unilateral disease of the kidneys was shown to produce hypertension and after removal of the kidney the hypertension disappeared. But after a very long search for unilateral kidney disease most people had come to the conclusion that the condition was very rare. It was very rare in cases of essential high blood pressure to be able to attribute the condition to a unilateral renal lesion, though such cases did occur and it was important to recognize them. But operation should not be performed until the intravenous pyelogram showed no excretion from one kidney and normal excretion from the other.

The Role of Renin

Dr. Mary Lockett discussed the role of renin and the renin-hypertensin system as an effector mechanism in experimental hypertension resulting from constriction of the renal artery. Renin had been demonstrated in the blood in many cases of experimental renal and essential hypertension, but its responsibility for the hypertension of renal ischaemia could not be said to have been clearly established by the methods of assay, and further work was needed to establish whether it was in fact the causative or the only causative agent. The results of slow renal infusion experiments raised some doubt as to whether a sustained increase of renin secretion could cause prolonged hypertension. After very considerable lowering of the blood pressure from trauma or from haemorrhage renin was shown to be liberated by the kidney and was demonstrated in the systemic blood. Although anoxaemia did not prevent the secretion of renin when the blood pressure was lowered, anoxaemia alone did not cause renin secretion. The properties of renin made it appear possible that renin was normally concerned with the regulation rather than the maintenance of normal blood pressure, and the development of tachyphylaxis gave cause for doubt whether excess of renin could be responsible for a persistently elevated blood pressure. The pressor action of renin, through the formation of hypertensin, had been shown to be due to its direct action on the blood vessels. Dr. Lockett also analysed the results of the work of investigators in North and South America and elsewhere and the varying terminology used.

Dr. W. N. Rogers asked whether anybody had tried thiouracil in cases of hypertension. Dr. Bruce Pearson said that in his experience the only benefit to be seen in medical treatment of hypertension was in patients who had crises during which the blood pressure was above its usual level. Such cases showed a response to dilator drugs. Nervous people with persistently high blood pressure would respond to sedative drugs or even to the removal of a cause of chronic anxiety, but people whose blood pressure rose when they got slightly excited tended to develop permanent hypertension. Dr. Thompson Hancock spoke of the use of potassium thiocyanate. One of the important things noticed was that in the bad cases in which it was used there was very often a greatly decreased excretion of thiocyanate, and unless one was very careful in such cases one might get a very high blood thiocyanate. Dr. H. Warren Crowe spoke of a recent paper in the *Lancet* on experimental prevention of nephrosclerosis with ammonium chloride. It was shown that desoxycorticosterone caused nephrosclerosis, and death of the rats was prevented by ammonium chloride in their drinking-water. This might account for the very satisfactory result of small doses of hydrochloric acid, given between meals, in reducing high blood-pressure. Ammonium chloride broke down into urea and HCl.

Sir Henry Tidy referred to the long period over which an organ might nurse an injury after the original cause has been removed. In renal lesions the opposite kidney might for a time show no effect and the blood pressure might fall, but once the damage had been done the effect persisted and might gradually multiply. He doubted whether the cases in which success was claimed for the unilateral operation had been observed long enough yet to say what their end might be. An example was to be found in the very large number of cases of trench nephritis in the first European war. With proper care and long rest the majority appeared to recover completely, but when a test was made on them ten years later it was found that the number showing renal deficiency had grown considerably over that shown in a previous test made about two years after the original attack. The organ once injured tended to nurse that injury and slowly to multiply its effects, and once this process had started it was likely to go on although the original cause had ceased to operate.

THE TRAINING OF CLINICAL TEACHERS

In the Section of Disease in Children (Royal Society of Medicine) on Oct. 26, Prof. Norman Capon took for the subject of his presidential address "The Training of Clinical Teachers." He prefaced his main discussion with the claim that paediatricians had adhered more closely to the tenets and discipline of the science and art of medicine than any of the specialists. The conditions of their work, both personal and professional, placed them in an unusually favourable position for promoting improvements in basic medicine.

How was it possible to ensure (Prof. Capon continued) that while the student learned what was essential in factual knowledge he was at the same time given a real education, a basis on which he could continue to build from his increasing experience? It was not enough to recommend a modification of the subjects which comprised his curriculum. Moreover, there was no certainty that a lecturer busily engaged in the treatment of the sick would remind the student that some people, at any rate, were healthy. It was from the teacher that the life-blood of education flowed. He quoted the article on "Education" in the *Encyclopaedia Britannica*:

> "No doubt all education is effected through the experiences of the educated, but it does not follow that all experiences are educative. . . . It follows that an education may be good or bad, and that its goodness or badness will be relative to the virtue, wisdom, and intelligence of the educator."

Prof. Capon suggested that in a given university a small group of senior clinical teachers, aided by one of the preclinical teachers and the professor of education, should undertake preliminary discussions with a view to organizing a vacation course for junior clinical teachers. The students would be restricted to, perhaps, 15, and would come from different centres, because discussion would form an important feature of the course, and so the views and habits of different medical schools should be represented. The following aspects of medical education would need to be covered, partly as lectures and partly as discussions and demonstrations: (1) The meaning of education, with some reference to educational methods in general. (2) The scope and aims of medical education, with special reference to (*a*) undergraduates and (*b*) graduates, including general practitioners, specialists and consultants, research workers, public health workers, and demonstrators. (3) The historical approach in medical education and the value of non-medical literature (as illustrating the value of one aspect of non-medical literature he mentioned two books—Francis Thompson's *Essay on Shelley*, and *Early One Morning*, by Walter de la Mare). (4) The artistic (or humanistic) approach. (5) The scientific method, with special reference to experimental inquiry, and its clinical application, including the technique of medical examination. (6) Elementary logic, including critical analysis of evidence and assessment of values. (7) The technique of clinical teaching. (8) The place of psychology in teaching. (9) The use of medical libraries. (10) The preparation of scientific reports and papers. He next showed a list of books which might usefully be studied before the class began—just a selection which had been of personal help to himself. They included Herbert Spencer's *Education*, Sir Thomas Browne's *Religio Medici*, Wilfred Trotter's *Collected Papers*, Sir William Osler's writings, Sir Thomas Lewis's *Clinical Science*, Francis Bacon's *Novum Organum*, W. S. Jevon's several books on logic, and many others, ancient and modern, covering the fields set out above.

It might be argued that clinical teachers had little time and sometimes little inclination for work which was not strictly technical or vocational. Lack of time was a defect likely to be corrected by a change of policy regarding teaching duties. As for lack of inclination, his own experience was that clinical teachers were most anxious to learn. Some might say that at present there were no clinical teachers who were equipped for the difficult task of conducting a course on the general lines he had just suggested. If the proposed course was to be effective it must be conducted mainly by practising clinicians, and it would be a mistaken policy to leave this basic education solely in the hands of clinicians whose experience was largely, if not solely, confined to hospitals.

The view had been put forward that teachers were born and could not be made, and that if a clinician was merely proficient in his professional work and knew his staff, the student learned by precept and example. He (Prof. Capon) gave place to no one in his respect for the first-class practising clinician; to him he represented the highest degree of excellence attained in the profession. But they did him less than justice if they assumed that by an active effort to broaden the basis of his knowledge and to cultivate wisdom he would thereby reduce his authority. A final question was whether a teacher could learn anything worth knowing of medical education in a three-weeks vacation course. He did not claim that such a course could do more than give a viewpoint, but here was the first stone of a foundation on which the teacher could build.

Discussion

In some discussion on the address Sir ADOLPHE ABRAHAMS, speaking as one who had been a teacher for 25 years and an examiner for 15, said that a clear distinction ought to be made between the two factors which were concerned in teaching—the teaching of students to pass examinations and the teaching of students to be practitioners of medicine. There were certain geniuses in the teaching world who could sustain this dual role, but he did not believe that a teacher could be "made"; the true teacher was naturally a teacher. No system of teaching would in itself produce the teacher-personality. He added that it was often urged that a general practitioner should be introduced from time to time to give students lessons in those particular parts of the art of medicine which were employed in general practice. He doubted whether that would be an advantage. The student who could follow the general practitioner on his rounds for a year would be in a different position, but that a general practitioner would be able to convey by ordinary teaching methods that particular skill which he possessed in the exercise of his practice seemed to him very unlikely.

Sir ERNEST ROCK CARLING suggested that they should ask themselves what kind of education they would like if they wished to be teachers of medicine. It must begin with the humanities. If a man had a real working knowledge of any of the Latin languages and literatures it was a very important beginning to his education. It was important that the teacher should understand the function of words and know what he was doing when he wrote or talked. Teachers in the future would have to do what they had not done in the past—namely, give instruction in the social aspects of medicine and in the maintenance and purpose of health. They would require a wide biological outlook on man, woman, and child. At some period in the apprenticeship which the future clinical teacher went through he must go into a place where research was conducted. He set very little value on the myriads of reports of research which were put out, particularly in America, but for some period the future teacher should work in a research laboratory. Then, since he must have the dual outlook in his teaching, he should himself have a full factual memorized knowledge of the whole literature and technical details of some small field, while no longer burdening his memory with factual material concerning the rest of medicine. Much could be learned by the teacher in travelling to clinics in this country and abroad, especially if he accompanied other teachers on such travels. This enabled him to keep right up to date in his work. Sir Ernest said that if he took on a chief assistant his plan would be for a year to lay himself out to teach him all he could; if the pupil was satisfactory he would continue him for a second year, during which he would expect him to help him, and if at the end of that second year he was still satisfactory he would in the third year put everything on his shoulders and merely stand by. Some plan along those lines would turn out a first-class set of young people. Dr. ALAN MONCRIEFF pointed out that in future a great deal of their teaching must be given to patients or potential patients, and the more one set out upon the care of the healthy as distinct from the care of the sick the more did medical practice become a purely educational process.

Correspondence

Demobilization of Doctors

SIR,—The rate of demobilization of medical officers in the Forces will be watched with critical eyes until demobilization is complete. So far there have been two phases. The first began with the end of the German War. The Royal College of Physicians was disturbed at that time by the general assumption that the demobilization of doctors in the Services could not keep pace with the release of other members of the Forces. It was even affirmed that the war with Japan, owing to the distances from our bases and the sickness rate, would be even more of a drain on medical man-power than the conflict in Europe and North Africa had been. Representations were made to those who had the power to act, and this phase came to an end when an order was given at the highest level for the demobilization, forthwith, of 1,600 doctors (the contribution from the Army was to be 1,100).

In consequence of this order the position was transformed overnight. It was no longer necessary to argue that the demobilization of doctors ought to keep pace with the release of other members of the Forces. It only remained now to make it possible by partial replacement for the Government to carry out its own policy.

Why is the partial replacement of demobilized officers necessary? Since the average age of Service doctors is higher than the rest of the Army, the number of doctors in the early groups for demobilization was correspondingly high. For example, when Group 11 had been demobilized 1,100 doctors were released—that is, 10% of all the doctors in the Army, while only 3% of the rest of the Army had been released; in other words, doctors were being demobilized three times as fast as the rest of the Army. Only when Group 26 was reached would the rate of demobilization be the same for both. But it is plain that the demobilization of the R.A.M.C., particularly of specialists, cannot continue indefinitely to outpace the rest of the Army, for the simple reason that a time would come when there would be no doctors left with the Forces. To ensure, then, that doctors can be released with their age groups, recruitment by the Central Medical War Committee must go on, otherwise medical demobilization will inevitably be slowed down. Replacement will of course be less difficult if an appreciable proportion of those who are eligible for release elect to remain in the Service. Of 1,100 doctors in the Army first due for demobilization, 250 have already asked for deferment of their release.

This, however, is a detail, if an important detail, in the machinery of demobilization. The second phase began with the order to which I have referred, which ensured that the demobilization of doctors would keep pace with that of other members of the Forces. In this phase it is the rate of demobilization of the combatant ranks which determines how quickly doctors are set free. That is alleged to depend on our commitments; it really depends on who is responsible for estimating those commitments. In time of war we are all content to leave this to the leaders of the Forces, but now that peace has come we have commitments on the home front which are even more urgent than those in occupied countries, and it is not within the province of the heads of the Services to assess those civil needs. If doctors are to be demobilized in time to meet civil emergencies, the estimates of the number of those who must be kept under arms will have to be revised by the Cabinet itself. We need more doctors in civil practice and we need them quickly. As things stand, by the end of this year the Army and the Royal Air Force will have released a quarter of their medical officers.

For some time the Royal College of Physicians has been considering what steps can be taken to ensure that in filling vacancies on the staffs of hospitals the claims of doctors now in the Services shall not be overlooked. Most of the hospitals in this country, large or small, have not filled the vacancies which have occurred in the last six years, and at the present time a large number of posts are vacant. The fort is being held by very senior members of the profession, many of whom for reasons of health or of years feel that they cannot go on now that the war is over. There is a danger that such vacancies may be filled before doctors in the Services are demobilized, and without their applications receiving the consideration they so plainly deserve. There is no simple remedy; there are many difficulties which confront anyone who is anxious to help. For example, hospitals may wish to interview the candidates, and we must at once concede that it will not be possible to bring applicants back from the armies of occupation for that purpose, for plainly if so much is conceded to one calling it cannot be denied to others. Once, however, an appointment is made, the procedure is simple. When a Service doctor is appointed to a vacancy on the staff of a hospital that hospital applies for his transfer to Category B for immediate release. Nor can we doubt that the Central Medical War Committee would support the release of the successful applicant, since the efficient staffing of hospitals is half the secret of an efficient health service.

When should these posts be advertised? The Demobilization Committee of this College believes that the vacancies ought to be staggered; for instance, one-third should be advertised immediately, one-third in January, 1946, and one-third on July 1, 1946. If such a suggestion is thought to be too rigid a hospital might be advised to advertise a reasonable proportion of such posts now, but in fairness to practitioners serving abroad no such appointments should be made for at least four months.

It matters little who gets the credit for speeding up the demobilization of doctors. Top marks ought to go to those members of the Coalition Government who were responsible for the order to which I have referred. I do not doubt that the present Cabinet will be equally sympathetic, for the health of the country is involved. It is not within the province of the Directors-General of the Medical Services to lay down the rate of demobilization, but once that has been decided I must testify to the energy and good will with which they proceeded to put their instructions into practice. They consented readily to serve on the College Demobilization Committee and welcomed junior members of their Services as colleagues on that committee. For my part, I owe a special debt of gratitude to General Hood, who made it possible for me and Dr. H. E. A. Boldero, the Registrar of the College, to go to Germany for five days with Prof. Stanley Davidson, to discuss on the spot problems associated with demobilization with more than half the medical officers in Germany, Holland, and Belgium.—I am, etc.,

London, S.W.1. **MORAN.**

Pernicious Anaemia and Cancer

SIR,—In 1933 (*Acta med. scand.*, 1933, **80**, 466; *Quart. J. Med.*, 1933, n.s., **2**, 281) I discussed the association of pernicious anaemia and cancer and added 6 cases of my own to the 29 definite cases collected from the literature at that time. Your annotation (*Journal*, 1944, **2**, 503) refers to the surprisingly high frequency (12.3%) of cancer of the stomach and pernicious anaemia noted by Kaplan and Rigler from an examination of post-mortem records and by Rigler, Kaplan, and Fink from an examination of a small series of patients radiologically. On looking through my own records I find a much smaller frequency; thus, in my first 1,600 consecutive patients with pernicious anaemia who have been under regular observation and treatment in my clinic during the last seventeen years I have observed only 28 patients (1.75%) with cancer; of these 12 (0.75%; 6 males and 6 females) had cancer of the stomach after 17, 11, 14, 5, 11, 8, 13, 5, 4, 1, 2, and 1 years respectively (an average of 7.66 years), while 1 developed pernicious anaemia at the age of 58 years, five years after the diagnosis and excision of a gastric cancer. Nine of the 12 were over 60 years of age when cancer was diagnosed.

In my series also 1 male with pernicious anaemia developed cancer of the caecum six years later, 2 (male aged 58; female aged 66) cancer of the colon after nine and six years respectively, while 2 females (aged 66 and 67 years) had pernicious anaemia diagnosed simultaneously with the diagnoses of cancer of the caecum and the colon respectively. Two patients with pernicious anaemia developed cancer of the pancreas after intervals of twelve and three years respectively, and 2 patients had pernicious anaemia with cancer of the throat, mouth, or tongue, 2 involved the uterus or vagina, and 1 had a breast cancer.

A radiological examination at six-monthly intervals of 1,600 patients is manifestly impossible under present conditions, and in my opinion is not necessary when these patients are under proper and regular supervision in an established clinic. It is important to be on the constant look-out for slight changes or recurrence of symptoms in adequately controlled patients with pernicious anaemia. Thus the gradual onset of vague dyspepsia, bowel disturbances, loss of weight, or anaemia in spite of adequate treatment with preparations of liver or stomach, and with the usual hydrochloric acid-pepsin mixture, should at once suggest further investigations, not only radiologically, but for the presence of occult blood in the faeces and changes in the fractional test meal.

As I have previously observed (*Quart. J. Med.*, loc. cit.) one must also be aware of the greater frequency of other diseases developing in or being associated with pernicious anaemia. Thus in the same 1,600 patients I have seen the development of diabetes mellitus in 28 patients, and thyroid disease (hyperthyroidism or myxoedema) in 36 patients. Here again slight changes in the well-being of the patient in the early stages, with the gradual onset later of the typical symptoms and signs of these three diseases, should immediately suggest further investigations and the appropriate additional treatments.

Obviously, with the considerable prolongation of life and the good prognosis in patients suffering from pernicious anaemia who are adequately and properly treated and kept under regular observations in special clinics, it must happen that these patients, in the ordinary course of things, will be liable to develop other diseases just as the normal individual may do if he lives long enough. Nevertheless, it is important constantly to keep in mind the possibility of complications such as these, so that early and proper treatment may prevent their further development and the impairment of the proper response of the pernicious anaemia to anti-anaemic therapy. It is essential that fully equipped haematological clinics should be established so that these cases and their treatments can be properly supervised at regular intervals, in the same way that diabetic clinics operate.—I am, etc.,

Royal Infirmary, Manchester. **JOHN F. WILKINSON.**

Effects of Choline

SIR,—The letter from J. A. Barclay, R. G. Kenney, and W. Trevor Cooke (Sept. 1, p. 298) and your subsequent leader (Oct. 27, p. 573) on the dosage and effects of choline chloride offer us an excuse to report the following experiments and observations.

The experiments were carried out in the attempt to confirm Davis's idea that heavy dosage with choline chloride depresses the blood count, and might possibly be used as the basis of a biological test for the activity of liver extracts for the treatment of pernicious anaemia. We took three rabbits and made daily counts of the red cells, white cells, haemoglobin, and reticulocytes. After a control period of one month we began treatment with single daily doses of choline chloride, 10 mg. per kilo by stomach tube. The dosage was increased at intervals of approximately ten days to 20 mg., 50 mg., and 100 mg. per kilo, but no change was observed in the behaviour of the rabbits or the condition of their blood. After forty days the dose was therefore increased to 500 mg. per kilo, but on the fifth day of this regime one of the rabbits had a convulsion and died shortly after receiving its daily dose of choline. There was no gross lesion post mortem, and there was no change in the blood count in any of the rabbits. Treatment was now suspended, and the other two rabbits were observed for a further fortnight, during which their blood counts remained as constant as ever.

Our conclusion from this small series of experiments was that it was unlikely that a simple method of assaying liver extracts could be devised along these lines. It is also evident that heavy dosage of choline chloride by mouth may be followed by sudden death, presumably due to stimulation of the parasympathetic nervous system. The fatal amount corresponds with a single dose of 30 grammes in man. This is not much more than the 20 grammes a day recommended by Barclay and his colleagues as the curative dose of choline chloride in man. When large amounts of choline chloride are administered in man the dose should therefore be fractionated, and the patient should be under careful supervision so that pharmacological antidotes can be administered in the event of a mishap.

We have given large doses of choline by mouth to two women with cirrhosis of the liver. A woman aged 58, with atrophic cirrhosis of non-alcoholic origin, received 5 g. three times a day for five weeks with no demonstrable effect, good or bad. A woman aged 22, with a more subacute type of cirrhosis, received the same dose, 5 g. t.d.s., p.c., but treatment had to be stopped at the end of a fortnight because of persistent nausea. In a third patient we used a much smaller dosage of choline chloride. This was a woman who contracted infective hepatitis during pregnancy and had been jaundiced for six weeks. She received choline chloride 2 g. a day for nearly a fortnight, and during this period her symptoms greatly improved.—We are, etc.,

SYLVIA M. LIVINGSTONE.
Oxford. L. J. WITTS.

Bronchial Embolism in Tuberculous Reinfection

SIR,—I think that your annotation on the pathogenesis of tuberculosis (Oct. 20, p. 537) dismisses the importance of bronchial embolism too lightly. You refer to some observations of mine and state: "The suggestion has been made that the frequent occurrence of reinfection lesions in the posterior parts of the upper lobes may be explained by the fact that foreign material, such as iodized oil, tends to be inhaled into these areas when the patient lies on his back and that tuberculous reinfection is therefore the result of bronchial embolism." This is not quite what I said. My first point was that the lung abscess affects the posterior subapical part of the upper lobe and the apical part of the lower lobes so frequently that an explanation is needed, and that bronchial embolism seems a reasonable and correct explanation. In order to show that bronchial embolism *could* cause a lesion in these sites my colleagues, F. Hodgkiss and H. O. Jones, and I (*Guy's Hosp. Rep.*, 1942, 91, 131) demonstrated that iodized oil could be made to enter these parts of the lung by simple posturing of the patient on his side or on his back. The association of inhalation of infected blood-clot, nasal secretions, etc., with a subsequent lung abscess is undoubted, and a parallel was then drawn with reinfection lesions in pulmonary tuberculosis. The radiological mimicry between a lung abscess and an acute tuberculous lesion may be so close that differential diagnosis may be impossible unless or until tubercle bacilli are found. This behaviour of tuberculosis is an observed clinical fact and demands an explanation. It was not my intention to suggest that it could be explained by inhalation experiments with iodized oil. These observations were made merely to show that such a mechanism is possible; the basis of the hypothesis rests on the study of numerous cases of undoubted bronchial embolism.

You also state that "it is difficult to see why the individual should be lying down when he acquires his infection." Here again I think the approach is incorrect. My argument was that it is *while the patient is lying down* that infection can occur and does occur in these parts of the lungs. That is a fact which must be accepted for further consideration and argument and is not to be dismissed by saying it is difficult to see why the individual should be lying down. You also state "a minute inhaled droplet might behave differently from a blob of iodized oil introduced artificially." I agree. The natural inference is that the mechanism of bronchial embolism is not by a "minute inhaled droplet"; the inhaled material must be larger in amount.

During working hours the larynx is on guard against inhalation of material from the pharynx; it is during sleep (and anaesthesia) that the guard is relaxed and material can enter the lungs. If the individual is sleeping in an infected room or ward, especially with a tuberculous subject, his nasal, oral, and pharyngeal mucus can certainly become infected and could then carry tubercle bacilli to the lungs. An individual exposed to infection during waking hours will sustain droplet infection of his nasal and pharyngeal mucosa; much of this will be washed away, but it is not unlikely that bacilli are held in crypts in lymphoid tissues and in other sites, and are liberated into mucus during rest and sleep and can then pass into the sites of election in the lungs. Saliva often collects in the mouth and dribbles on to the pillow during sleep; it must be equally easy for it to run back into the pharynx. Germs can reach the patient by droplet infection, but there is little evidence that they reach the lungs solely by droplet infection. I suggest the evidence points to their reaching the lungs by inhalation of gross material from the nose and pharynx, and particularly during sleep.—I am, etc.,

Guy's Hospital, S.E.1. R. C. BROCK.

Sequelae of Emphysematous Lung

SIR,—I was very interested in the article on massive surgical emphysema, pneumothorax, and pneumoperitoneum by Dr. Ronald Jones (Oct. 20, p. 530), in which he described in Case I an unusual sequence of events after intubation of the trachea with the bronchoscope. He states that after intubation there developed a surgical emphysema of the face and neck with deep cyanosis, which was associated with swollen tracheo-bronchial mucosa and a complete blockage of the right and a partial blockage of the left main bronchus. Four days later a radiograph of the chest and abdomen showed a right pneumothorax and pneumoperitoneum. Ten days later the pneumothorax and pneumoperitoneum had disappeared. Truly a problem at first sight.

I would venture to give a probable explanation in this case. It would appear to me that the outstanding feature was not so much possible damage to the tracheo-bronchial tree, causing a pneumomediastinum, as the blocking of the main bronchi. When this latter occurs over a short period of time there is a ball-valve action, with marked increase in the intrapulmonic pressure—i.e., more air enters the lung than can escape. Having achieved this temporary state of a ballooned emphysematous lung there are two alternative catastrophes, and both may happen: (*a*) a peripheral alveolus ruptures into the pleural space, causing a pneumothorax; (*b*) the rupture may take place through both visceral and parietal pleura in the region of the mediastinum, causing pneumomediastinum. I have seen pneumomediastinum occur in post-operative atelectasis, due to the forced expiratory coughing effect, which attempts to clear the bronchus and leads to rupture of the mediastinal pleura.

Having established pneumomediastinum the free gas or air has an interesting roving commission. It may travel in a cephalic direction or caudally: (1) in a cephalic direction as surgical emphysema into the neck, shoulders, and face; (2) caudally as two linear paravertebral gaseous shadows into the retroperitoneal space of the abdomen via the route of the great vessels through the diaphragm.

The retroperitoneal gas appears first in the subdiaphragmatic region, and radiographically and clinically is indistinguishable from pneumoperitoneum. There would be a tympanitic note in the upper abdomen, and the insertion of a needle into the flanks would allow the escape of gas. The retroperitoneal gas also passes into the flanks and perirenal region. The perirenal distribution is an important differential diagnostic factor from pneumoperitoneum. As Dr. Jones states, there is no communication between the retroperitoneal space and the peritoneal cavity, unless some obscure accident causes a breach in the peritoneum. This is unlikely. I feel that Case I was probably a marked degree of retroperitoneal gas simulating pneumoperitoneum. An interesting diagnostic test would have decided this point. In pneumoperitoneum the gaseous sites move to the most dependent portions when the patient is changed from the vertical to the lateral decubitus, but retroperitoneal gas remains fixed in its loose areolar space.

In retroperitoneal perforations of the gastro-intestinal tract, fortunately rare, the reverse of the above retroperitoneal pathway holds good—i.e., perirenal, the flanks, subdiaphragmatic, and on with the great vessels through the diaphragm into the mediastinum and neck. An acute abdomen plus surgical emphysema spells only one thing—a retroperitoneal perforation somewhere in the gastro-intestinal tract. A more detailed description of the behaviour of retro- and intra-peritoneal gas will be found in my address to the annual meeting of the Faculty of Radiologists under the title of "Investigation of Free Gas in the Peritoneal Cavity." This has gone to press and should appear in the November issue of the *British Journal of Radiology*.—I am, etc.,

Hull. J. E. BANNEN.

Epidemic Diarrhoea and Vomiting

SIR,—The account by Drs. George Brown, G. J. Crawford, and Lois Stent (Oct. 20, p. 524) of the outbreak last spring and summer in Salford tallies closely with the epidemic experienced in the East Riding over the same period. A very rough estimate suggests that perhaps 20,000 cases occurred in this county of only some 190,000 population, with possibly 1 in 4 being seen by a doctor. Recovery in a few days was apparently invariable, so that few faecal or other specimens were sent for examination except on the request of the laboratory. Though *B. sonnei* had shortly before been readily recovered from two-thirds of cases of a local dysentery outbreak, pathogenic organisms were noticeably absent from the 28 sample specimens from this widespread condition, and no agglutinations to *B. sonnei* were found in the 12 cases examined in a mental hospital group. A questionary to a few doctors scattered over the county elicited a clinical picture like that of the above authors, with liquid diarrhoea lasting three to four days in 100% of cases, vomiting for half a day to three days in 20% to 50%, and little else but a variable abdominal discomfort. It frequently spread through a family or community group, with intervals between cases of one to five days, probably more often spreading among those in contact than among those eating from a common source.

Such considerable economic loss as there has been this year, with the possibility of recurrence as in the Philadelphia outbreak described by Reimann, which has taken place the last two autumns, makes especially opportune the study of the Salford doctors.—I am, etc.,

Driffield Emergency Hospital, York. H. F. BARNARD.

REFERENCE

Reimann, H. A., Hodges, J. H., and Price, A. H. (1945). *J. Amer. med. Ass.*, **127**, 1.

SIR,—It was with a sigh of relief that I read the article by Drs. George Brown, G. J. Crawford, and Lois Stent (Oct 20, p. 524); and my gratitude to them is great. There was the exact description of an "epidemic" which has dogged my footsteps with its endemicity for all my ten years here. In Bedworth, a town of some 20,000 people, it has flared up about once a year—not at any set season—and often trespasses a bit into a neighbouring city. At each flare-up I should guess that 10% of the total population is affected, and I think that partial immunity develops. As for diagnosis, its maddeningly exasperating bacteriological negativeness sank into me eight or nine years ago (and my early efforts, which included sending a few cases into a city hospital, apparently did not start epidemics there).

Its absolute "non-fatalness" is mirrored in the fact that my patients and I have developed for it a pet name; we call it "Bed'orth disease"—i.e., we have developed a mental immunity, greater, fortunately, than our physical immunity. I believe it has been termed locally "gastric influenza," this name being started by a medical new-comer to the district, who was, perhaps, slightly less immune. As to treatment, it was early obvious (about 1936) that the traditional preliminary dose of ol. ric. was wrong; the treatment advocated at Salford has long been used here, plus the first 24 hours with water only (no milk) and in bed.

An interesting confirmation of the theory that some immunity develops has occurred this year. A community new to the district (240 people in a resident training college) arrived on June 1. On July 2 77 of them—i.e., 33%—reported sick, all within a few hours. The outbreak ran its usual mild course, and "mental immunity" was quickly caught by infection from their M.O. (a local practitioner). The college christened their unwelcome and uninvited local guest "the plague." The probability of personal partial immunity being possible is based on myself as a patient. My first attack (1936) was the worst, and subsequent attacks have become progressively milder. My first was very acute (with vomiting) for 24 hours; as I could not lie up I was mildly afflicted thereafter for two months.

I shall be interested to hear whether other districts of England, encouraged on to paper by the Salford report, have similar past histories.—I am, etc.,

Bedworth, Warwickshire. JOYCE HENRY.

SIR,—The writers of the article on epidemic diarrhoea (Oct. 20, p. 524) are undoubtedly correct in their surmise of the universality of this harmless type of diarrhoea. It would be interesting and highly instructive to know why these epidemics of one thing and another suddenly flare up all over the place *at the same time*. There is something of a superstition among we "old chaps," that grows with further experience, that many troubles which cannot by any stretch of the imagination be regarded as infections come in waves—e.g., accidents, births, deaths, particular types of non-infectious illness. I have recently, for example, seen three cases of coma within two days. It is months since I saw one before. Is this sort of thing really coincidence? It would be extremely interesting to keep track of such happenings over a wide field for some time, to see if we get waves or epidemics of such non-infectious happenings over wide areas at the same time. I suspect this to be the case, and suggest that the matter be investigated. Should this turn out to be so, it would suggest some common factor operating over wide areas at any given time—a factor that from the magnitude of the area involved could only be something that affected perhaps the human nervous system and through it the whole body economy.

I suggest that the cause is likely to be found in Lakhovsky's theory that cosmic radiation around the 8-metre band is responsible for the supply of electromagnetic energy which drives the body and its cells, and that meteorological and other conditions which vary the intensity of these radiations greatly modify the activity and even the health of the body cells. In his book *The Secret of Life* Lakhovsky appears to make out a very good case for his theory. If such life-giving electromagnetic radiation is subject to disturbances due to meteorological conditions over a wide area, why not, in the same areas, variations in the sensitiveness of the human nervous system leading at times to accident-proneness, the onset of labour, conditions favourable to the onset of certain types of disease, etc.? Here surely is a field for investigation that gives promise of being productive of most interesting and far-reaching results, not the least of which would be to settle the question of the "old chaps'" superstitions once and for all.—I am, etc.,

HUGH L. MACKINTOSH.

Pasteurization of Milk

SIR,—As one closely associated with the milk problem in medicine I feel that the letter written by Dr. Tudor Edmunds (Sept. 15, p. 367) calls for some comment. He is suggesting that pasteurization should be only a temporary measure, the main reason given being that the development of good herds and dairies will be neglected and that people will tend to call anything that is pasteurized perfect milk. I would refer the author to Prof. G. S. Wilson's very detailed report to the British Government on pasteurization of milk (1942).

I wish to state very emphatically that even if one attains clinically perfect herds and dairies it is still impossible to have 100% perfect milk. Even in a tuberculin-tested herd, or any first-class herd, tubercle bacillus, *Bacillus abortus* of Bang, not to mention all the streptococci, may abound. Now in Great Britain all city milk is of necessity "bulked"—tuberculin-tested and non-tuberculin-tested. One infected cow can, therefore, grossly infect up to 20,000 gallons of milk, and the poor unfortunate individual is drinking it under the impression that it is absolutely bacteria-free clean milk.

U.S.A. public health literature makes abundantly clear the great reduction that occurs in infectious diseases and tuberculosis when pasteurized milk is used. Conditions in U.S. dairies are much better than will obtain here for a great many years, if ever. The cost of pasteurization is minute when put against the cost of treating infectious diseases and tuberculosis, not to mention the damage and loss of life. The result is permanent, safe, and lasting. Pasteurized sewage is at least sterile and is probably preferable to tuberculin-tested milk with typhoid bacilli. Something practical for a change like permanent pasteurization is much better than theorizing on a beautiful scheme that gets no further than the M.O.H.'s desk.—I am, etc.,

RONALD R. J. R. CLARKE,
Tuberculosis Hospital, Machynlleth. Assistant Tuberculosis Officer.

The Child with Frequent Colds

SIR,—I am sure most general practitioners will have read the article by Drs. D. H. Irwin and E. Frankel on the child with frequent colds (Oct. 27, p. 566) with great interest and equally great disappointment that their conclusion as to treatment is that it is "entirely a problem for the ear-nose-and-throat surgeon." Although the authors say note was taken of the environment of the children, no further reference is made to this essentially important factor save a statement that the majority of the children came from middle- and artisan-class families. What would be thought of a psychiatrist at a child-guidance clinic if in investigating cases no study was made of the children's parents and sibs and general family and social background? Yet surely the child with frequent colds is as much a victim of his family and environment as his fellow with difficult or abnormal social behaviour. Little headway will be made with the problem until it is investigated on these broader lines and a serious endeavour is made to find the source of recurrent infections and not just to study the results.

In my experience as a general practitioner children with recurrent colds and throat infections can nearly all be classified in one of two groups: (1) those who commence their infection in infancy, often below the age of 9 months, and have attacks with such frequency that they are rarely well though usually ambulant; (2) those children whose infection starts when they first attend school.

The origin of infection of children in Group 1 is usually some older member of the family with a chronically infected throat or nose. They are largely of the poorer classes, where such factors as small rooms and overcrowding accentuate the intensity of infection, but they can also be found in higher social strata. One serious result of these chronically catarrhal and coughing children is that the mothers are no longer able to judge their state of health, and will send the children to school with severe colds and in the early stages of more severe infections, such as measles and pneumonia. Many of the children in this group would be much more benefited by the removal of their parents' tonsils than their own. The children in Group 2 get their frequent colds from the large mass of infection brought to school by the children in Group 1. This is helped by old, overcrowded, and badly ventilated school buildings. As the children grow through adolescence their colds become less frequent, but many develop permanently infected sinuses. They are the parents of the next generation, and so the cycle is complete.

This vast problem has many more aspects than can be dealt with in a letter, but I think it is only by the study, not of the individual child, but of the family in its biological setting (to use the words of Dr. Innes Pearse), that progress can be made.—I am, etc.,

Sittingbourne. F. M. MALLINSON.

SIR,—The article by Drs. D. H. Irwin and E. Frankel (Oct. 27, p. 566) appears to be a good example of modern medicine gone wrong. We are told the results of many investigations made, except the most important. Does the child normally keep its nose clear and breathe through it with the mouth shut? Apart from the statement that "in 33 cases the mothers complained that their children snored at night and were mouth-breathers," I can find no mention of this most important factor. Nor is it clear to me from the above sentence whether other children were mouth-breathers, though their mothers failed to complain about it; nor whether the mouth-breathing referred to is at night only, or in the day too; nor whether it was their usual practice or just when they had a cold. Nor is it emphasized that it is more than usually important to keep the nose clear and breathe through it when the child has a cold. The beneficial or other results of removal of tonsils and adenoids depend, too, mainly on this factor.

Lastly the authors say this "is entirely a problem for the ear-nose-and-throat surgeon, who should keep these children under supervision in a special clinic"; they might add "and teach them adequately to blow their noses." This is just the sort of thing the neglectful parents wish: they would do better to read page 165 in the current number of the *Health Education Journal*.—I am, etc.,

Pettswood, Kent. G. C. MILNER.

Psychosomatic Reactions

SIR,—Your annotation "A New Reaction to Emotion" (Oct. 13, p. 504) asked two extremely pertinent questions. It is becoming increasingly evident on clinical grounds that the suggestions inferred from such questions are indeed "probably true," in that there are other important physiological responses to emotional stimuli; and that there are other, as yet unidentified, hormonal activities associated with such stimuli, not only on the positive side, as shown so effectively by Verney and his co-workers, but also as a (? exhaustion) hypofunctioning along the same psychosomatic train of events.

Similar associations in clinical research tend to show that the prevalent curse of non-articular rheumatism may be intimately related to a psychosomatic reaction. While it has been recognized for many years that emotional or mental stress factors are operative in rheumatic cases, it has become evident during these last two years that there is certainly a type of generalized "fibrositis" showing a typical syndrome, of which the fibrositis is but a single symptomatic unit, and a unit of a syndrome closely associated with pituitary hypofunction. That this syndrome, in history, signs, and symptoms, is so strictly similar in each of these cases points to the probable association of the pituitary, which may well have a wider significance to rheumatic cases in general.

These cases have been prominent in their numbers recently, due, it is thought, to six years of emotional stimuli in various major and minor forms from bombs to queues. Contrary to the reaction described by Verney, which no doubt occurred at the time in these cases in a typical manner during the period of prolonged stimuli, they then develop the rheumatic complaint characterized by a hypofunction of the posterior pituitary—i.e., diuresis, polyuria, polydipsia, and an indurated swelling of typical tissues due to fluid retention leading eventually to an extremely painful state, which, for want of a better term, one designates an acute rheumatic panniculitis. Features of this syndrome other than fibrositis are tiredness, lassitude, both physical and mental, spontaneous or excessive bruising on minor trauma, flatulence, menopausal symptoms in women, increase in weight, rather rapid and weak pulse, and a blood pressure rather lower than normal. Some of these features may be ascribed to exhaustion of the sympathetic autonomic nervous system, but some are more directly attributable to pituitary hormonal control.

In my cases it has been found that the antidiuretic control may be rapidly regained by giving the posterior pituitary hormone in the preparation pitressin, but without evident effect on the rheumatic symptoms. *X*-ray examination shows typically normal outlines to the fossa. It is reasonable to postulate, therefore, in reference to your question that there are other hormones of the pituitary or hypothalamus probably associated in this psychosomatic cycle of physiological events. "Directed team research" is avidly and hopefully working along such lines, and for the moment, as a result of much biochemical research upon the blood, interest is now centred round the adrenocortical hormone of the anterior pituitary.

While in a more direct way to answer your question, a similar emotional psychosomatic reaction has been delineated as a laboratory biochemical reaction upon certain hepatic functions, drawing an interesting graph, since before the fall of Singapore, which closely parallels the emotional state of the populus in its reaction to bombs, politics, and peace.

The purpose of this letter, Sir, is therefore to underline the importance of the questions you have postulated, to comment upon the real value of these annotation reviews, and to stimulate research workers on non-articular rheumatism to review the very many closely associated features recorded of pituitary function in the light of their own particular field; and to summarize by stating that in the final evaluation of the pathogenesis of non-articular rheumatism an answer will probably have to be found to the further question: What functional activity or lack of activity in the hypophysis or hypothalamus can be shown to be paramount in these severe cases of generalized fibrositis?—I am, etc.,

London, W.1. HARRY COKE.

Surgical Catgut

SIR,—I believe I am correct in saying that before the war a large proportion of surgeons in this country used catgut made by a well-known American firm. This has been unobtainable during the war, so that those of us who used this catgut have had to use English makes which we had previously found unsatisfactory. The makers in this country have had a wonderful opportunity during the war of getting their makes established as favourites with surgeons, and thus increasing their sales and maintaining them when the American make is again available.

I have yet to use a British make of catgut which can be relied upon to be consistent in size and strength: the contents of tubes of the same nominal strength are often exasperatingly variable. This inconsistency seems to have increased considerably since the numbering of the sizes was changed a little time ago. The makers are aware of this variability in strength and size, for they make excuses for it. It may be difficult to overcome, but it is possible, as the Americans have shown.

Theatre sisters and retailers of catgut have told me that they will welcome the return of the American catgut so that complaints (and curses) from surgeons about catgut will cease. Is it too much to hope that now, at the eleventh hour, the British catgut-makers will endeavour to standardize their catgut so that this commodity need not be largely imported? There has been a large return to linen and cotton thread, but catgut is still necessary in places. Why, too, cannot the English makers maintain a standard length of tube for catgut? Many tubes will not fit into surgeons' sterile catgut containers.—I am, etc.,

London, W.1. JOHN HOSFORD.

Haematuria following Injection for Varicose Veins

SIR,—Surely the haematuria which sometimes occurs following ethamolin injection of varicose veins and referred to by Mr. Harold Dodd (Oct. 13, p. 510) is ominous. I met with one such case: a patient whom I injected several times as an out-patient and who consistently got profuse haematuria within the first twenty-four hours of injection. I have never been able to get an explanation of the occurrences. I had never heard of a similar incident until I read Mr. Dodd's letter. Can he suggest the pathogenesis?—I am, etc.,

London, S.E.13. W. KEVIN BARRY.

Chin-Chin!

SIR,—Your correspondent "Four Chins" in his interesting letter (Oct. 20, p. 547) advises "any fat person to count up the calories consumed regularly every day for some years back"; this, for a layman, would prove to be a rather tedious and difficult task. About 15 or 20 years ago "slimming" was the vogue, and patients occasionally consulted me regarding their over-weight. My simple but effective plan was to give the applicant on a slip of paper his or her normal weight for sex, age, and height, with instructions gradually to reduce in amount at each meal the ordinary diet, until the normal level was reached and maintained. Advice was given as to checking the weight on a reliable machine at regular intervals, say, weekly or monthly, and recording it, any difference in weight of clothing being noted. Those of us who were in practice at the time mentioned may remember patients who, from total avoidance of certain kinds of food which they believed were "fattening," induced some degree of ill-health, and we know that adiposity may have other causes than that of overheating.—I am, etc.,

Burgess Hill. W. W. SHRUBSHALL.

Psychiatry in the Services

SIR,—I was extremely interested in the letter by Wing Cmdr. K. Bergin. I would like to add my quota of experiences and express my opinion on the subject.

There is no doubt that the responsibility as regards the disposal of all psychiatric patients lies largely in the hands of the regimental medical officer. He needs to sort out his cases judiciously and exercise care when initiating a probable series of events which might culminate in "the final scene" of invaliding. I have never had a case returned to me by the psychiatrist without a recommendation of down-grading, and this has been the experience of many of my colleagues with whom I have discussed the matter. Presumably the psychiatrist—who, after all, has only seen the man for the first time in an interview lasting about half an hour—justifiably assumes that the patient has been regularly observed by the company commander and the medical officer, and that the latter has concluded that down-grading is the only possible solution. The ultimate problem is, therefore, the determination of the category in which the patient is to be placed, and this is decided by the higher authority.

I, myself, have been very cynical of some of these cases. When a man with ? anxiety neurosis relates his symptoms I almost invariably give him a little "pep" talk and ask him to report again in a week if there is no improvement. During this time I request that the company commander keep him under his observation. If the man returns—often he does not, my initial chat with him having been apparently successful—and says that the symptoms are the same or worse, I decide from my own observations and those of the company commander whether he should be sent to a psychiatrist.

The assessment of psychological dysfunction in the Army I find extremely difficult, and many so-called sufferers are often regarded as having "got away with it," especially when their condition after invaliding has been so much improved. But I am certain that in many cases invaliding in itself is the only successful treatment. In peacetime jobs these men have been relatively happy, and their tolerance of change is inherently low. When the change is of a military nature they, consciously or subconsciously, try every means to enable them to revert to their previous mode of existence by getting themselves invalided or their medical category reduced. Failure to obtain their objective will probably act as the seed for more severe psychogenic disorder. I consider, therefore, that many of these men who have been therapeutically down-graded or returned to civil employment and have benefited therefrom are true cases of low mental tolerance. Employing them as A1 soldiers might be risking irreversible mental ill-health.

I regret that there are many who have with repulsive cunning secured a far more tolerable existence than the average soldier. But until diagnosis in psychiatry is made more exact (and the ideal is extremely difficult to perfect), these cases are inevitable and will always infest the community of true sufferers, who might by the over-sceptical medical officer be regarded as malingerers and treated accordingly.—I am, etc.,

WILLIAM BRAND,
Uckfield, Sussex. Capt., R.A.M.C. (R.M.O.).

SIR,—In these enlightened days it is indeed disheartening to read Wing Cmdr. Bergin's comments on the disposal of psychoneurotics in the Services. That he has "become very cynical of these cases" is surely to admit defeat. His catalogue of neurotic symptoms is comprehensive, but his understanding of their mechanism is unfortunately coloured by an attitude of mediaeval mysticism. He is apparently obsessed by the notion that the psychoneurotic is possessed by the devil and that he is endeavouring with this preternatural skill to outwit the poor medical officer. In truth, such a battle is the creation of a closed mind.

Very few of these patients are malingerers. And in any case, in view of his maladaptation, should we not also treat the malingerer as a psychiatric problem? One does not have to be a Sigmund Freud or invoke the awesome precepts of the Oedipus complex to appreciate how such psychoneurotic manifestations as chronic headache, dyspepsia, palpitations, bronchospasm, etc., may arise. They are the physical expression of abnormal intrapsychic tension in the absence of structural changes. Indeed, they may be regarded as a valve-mechanism that acts as a safeguard against complete emotional blow-out.

In considering the nature of abnormal intrapsychic tension in Service personnel we may conveniently recognize two factors: (1) psychoneurotic predisposition; and (2) environmental stress. I think Wing Cmdr. Bergin will agree that Service life has its stresses. By far the great majority of people succeed in weathering this little storm, but those with neurotic predisposition "have the pants taken off them," laying them bare in all their emotional inadequacy. Such members are temperamentally unsuited to Service life, though, of course, they may be able to achieve equilibrium in some relatively quiet backwater in civil life.

It is high time we realized that emotional illness can be just as severely incapacitating as organic illness.—I am, etc.,

A. BALFOUR SCLARE,
Flying Officer, R.A.F.V.R.

Silverstone, Northants.

SIR,—Wing Cmdr. K. G. Bergin raises some interesting points which have not been dealt with by subsequent correspondence. All station and unit medical officers in the R.A.F. will sympathize with him, but it is unfair to blame the psychiatrists for becoming, as they have done, "the porter at the back door." It is true that many people who are unsatisfactory in the Services and who get invalided on grounds that are obviously not connected with loyalty are invalided on the recommendation of the psychiatrists, but it should be remembered that they were not taken in on the recommendation of the psychiatrists.

Where does the fault lie? Surely it lies with the civilization which we have built up. For years before the war, through the Press and other means, the danger of living and the necessity to conserve and preserve life had been stressed. One has only to read the advertisements of the Safety First Association, to say nothing of the advertisements of those who sold preparations for the prevention of constipation and "other evils of mankind." Self-preservation is a natural instinct. Courage or the anti-self-preservation factor is not an instinct but a factor to be inculcated. It is therefore really surprising that we have had as many courageous people as we have had.

In industry before the war it was being increasingly recognized that misfits in employment did not lead to better work or increased production. Similarly, in the Services misfits do not lead to better individual or collective work. War does bring a necessity sometimes to make pegs fit holes not designed for them. To what extent we are prepared to ram the pegs in is another matter. Other nations, perhaps, are prepared to do this by inhuman means. That, surely, is one of the things we have been fighting against. It is a problem of society and not of the Services. Admittedly it is unsatisfactory to the more loyal to see the less loyal getting out on psychiatric grounds, but this does not make these psychiatric grounds any less justifiable in the interests of the individual and of the team which their presence has been seriously handicapping. The remedy lies in better psychiatric control of our outlook and civilization. The fact that Wing Cmdr. Bergin gets good results by disciplinary action does not prove that disciplinary action is the method in any but a very small percentage of cases.—I am, etc.,

London, W.C.2. RICHARD W. DURAND.

SIR,—Wing Cmdr. K. G. Bergin's letter interested me greatly, for I have long had somewhat similar views with regard to the methods of dealing with cases of the "escape mechanism" type described by him. I can also confirm by examples that as soon as an airman obtains his desire a startling transformation occurs and his symptoms appear to vanish completely, but I have noticed this happen in a good number of cases not invalided but whose category had been lowered to home service only. I have seen airmen, frequent attenders on sick parade, be temporarily down-graded and never be seen for the next six months, then to reappear with symptoms as soon as they realize they may be up-graded and be fit for over-seas again.

I cannot, therefore, agree that "the first step on the downward path is now taken" as soon as the medical category is lowered and the patient's oversea service restricted. In my view a temporary lowering of category to service at home enables many patients to carry on serving, and since the end of hostilities I have also been surprised at the number who express a desire to have their original category restored after their period of temporary down-grading has expired. This would appear to indicate that in the lower age-service release groups patients have come to the conclusion that they are now "safe" so far as oversea service is concerned and symptoms are no longer necessary. There is also the fact that they have to find civilian employment soon, when a "reduced" category may be a drawback.

The answer, so far as I can see, is to distinguish where possible between those showing mainly "affective" symptoms and those showing mainly symptoms of hysteria (the "escape mechanism" type), for it is this latter who apparently do well with a little more discipline and benefit more by action by the executive rather than by the medical officer. The former, in my opinion, are a bad risk and ought to be invalided before they really develop fully: it is they who will be a problem in "civvy street."—I am, etc.,

Tealing. J. LAURIE, Squad. Ldr.

Medicine in the U.S.S.R.

SIR,—When I wrote to you on Oct. 2 in connexion with Dr. Norman Henderson's letter (Sept. 1, p. 302) I assumed that, as is usually done, Dr. Henderson would in reply put forward some facts in explanation of his statement: ". . . in the event of a full-time medical service failing (as it has to a large measure in Russia) . . ." In the *Journal* of Oct. 13 (p. 514) you printed my letter together with Dr. Henderson's reply to Dr. Culbert and Dr. Fieldman. Evidently you, Sir, took it that this reply would serve as an answer to my letter as well, and thus the question could be considered as closed. Since to me, as a Soviet doctor, this method of criticism in a medical press appears strange, I feel compelled to draw attention to the following facts.

(1) In his reply to Drs. Culbert and Fieldman Dr. Henderson did not prove by facts or basic investigation of the subject of discussion anything that would give foundation for his allegation. As such data do not exist Dr. Henderson seems to draw his own inferences from literary sources such as *Red Surgeon* by Borodin, and to refer his statement to Prof. A. Semashko's quotation: "The most popular doctors and professors are able to earn extra money from private medical practice in addition to their salary from the State." Even if the above is a quotation from Prof. A. Semashko, one wonders why Dr. Henderson wishes to bring this statement as evidence of the failure of full-time medical service in the U.S.S.R. Although private medical practices exist in the U.S.S.R. on a legal basis, that does not, to any extent, affect the efficiency of full-time medical service. Trying to escape the difficult position created by the question of full-time medical service, Dr. Henderson suddenly turns to the Institute of Experimental Medicine in Moscow, and attempts in one sentence to bring into a doubtful light the activities of this, one of the oldest and greatest medico-scientific institutions of the Soviet Union. It is quite obvious in all his inferences Dr. Henderson lacks a sober attitude to the matter in question.

(2) I have found nothing in the February, 1945, issue of the *American Review of Soviet Medicine* that would corroborate Dr. Henderson's criticism of the Soviet medical service. It therefore appears that Dr. Henderson is not correct in referring to that journal.

(3) We consider that the mutual interests of the medical workers of Great Britain and the Soviet Union deserve to be given a more serious and basic study of medical questions in both countries than Dr. Henderson does. Only then mutual help and fundamental criticism will bring even nearer the medical workers of Great Britain and the U.S.S.R.

Although you state that correspondence on this subject cannot be continued, I feel it is most necessary to have this letter published.—I am, etc.,

London, W.2. S. SARKISOV.

⁂ Out of respect for Prof. Sarkisov we allow him a last word. Dr. Henderson has already had much space and must be content with the reply he has given to two other readers who challenged his statement about Russia.—ED., *B.M.J.*

Obituary

JAMES SHERREN, C.B.E., F.R.C.S.

Mr. James Sherren, consulting surgeon to the London Hospital, who died at his home, White Barn, Broadstone, Dorset, on Oct. 29 after a long illness, had a remarkable career.

He was born in 1872 at Weymouth, the eldest son of J. A. Sherren, and went to school at Weymouth College. With an inborn love of the sea and ships he left school early and served before the mast. After hard and testing experiences at sea he quitted that life to enter as a medical student at the London Hospital, winning distinction in anatomy and physiology and scholarships in medicine and obstetrics. He qualified at the age of 27, and took the F.R.C.S. in 1900. His ability soon made its mark and he was appointed demonstrator of anatomy and surgical tutor in the Medical College, and in 1902 was elected assistant surgeon to the hospital. This was at a time when abdominal surgery was making rapid progress, and Sherren, following the footprints of Frederick Treves, took every opportunity to gain experience in this branch of work. He also did pioneer research with Henry Head on the peripheral nervous system and published in 1908 a monograph on *Injuries of Nerves and their Treatment.* During the war of 1914–18 he served with the rank of colonel, A.M.S., as consulting surgeon attached to the War Office, surgeon to the King George Military Hospital and to the King Edward VII Hospital for Officers, and consulting surgeon to the Yarrow Military Hospital in Broadstairs. His war services were rewarded by the C.B.E. in 1919.

[*Lafayette, Ltd.*

At the Royal College of Surgeons of England he had been Erasmus Wilson lecturer in 1906, Hunterian professor in 1920, and Bradshaw lecturer in 1925 on gastro-jejunostomy. He examined in anatomy for the Primary Fellowship, was for a short period a member of the Court of Examiners, served on the Council of the College from 1917 to 1926, and as vice-president for two years; he examined also in surgery for the University of London and was a member of the Senate. At the age of 54, and at the peak of his surgical career, with a very large consulting and operative practice, Sherren suddenly gave up his hospital appointments, left London, and went back to sea as a ship's medical officer. When he finally settled on his estate at Broadstone he did not altogether abandon professional work but gave service for some years as surgeon to the Cornelia and East Dorset Hospital at Poole.

He joined the British Medical Association in 1906 and held office as vice-president of the Section of Surgery at the Annual Meeting in Nottingham in 1926, just before his retirement from work in London. Apart from the book on nerve injuries he contributed to Choyce's *System of Surgery* and published *Lectures on the Surgery of the Stomach and Duodenum* in 1921; he had also been joint editor of Sir Robert Hutchison's *Index of Treatment*, and wrote some of the articles in the earlier editions.

Mr. H. S. Souttar writes:

The passing of James Sherren closes a unique career and removes a figure memorable in the story of the London Hospital. To go to sea before the mast, to rise in a few years to be first mate on one of the great shipping lines with a master's certificate, to leave the sea, start afresh as a medical student, and reach the surgical staff of a great London teaching hospital by the age of 30, argue ability and driving force of the rarest quality. To those of us who had the good fortune to know him at the London Hospital those were his most distinctive characters, and we still feel the power of their infection. He was a great surgeon and a great teacher, but it will always be as a real man that we shall remember him.

He qualified in 1899, and after that his progress was without parallel. After holding all three house appointments, H.P., H.S., and R.A., he became surgical registrar in succession to Henry Newland, whose career in Australia was to emulate his own, but he held this post for only one year, for in 1902 he was appointed to the surgical staff of the hospital. In spite of a very busy post he managed to find time for a research with Henry Head upon injuries to the peripheral nerves which still remains of fundamental value, but with the death of H. L. Barnard in 1908 he took up the field of abdominal surgery to which Barnard had made such brilliant contributions. He had found his true vocation, and it is as one of the creators of modern gastric surgery that his name will be remembered.

He developed a large surgical practice, but he never allowed it to interfere with his hospital work, and if his demands upon his assistants were sometimes reminiscent of his early days at sea, he never spared himself, and served his patients with a rare devotion. Yet he still had one other great passion in music, for he was a fine performer on the violin, and every week a group of professionals met at his house to spend an evening in classical quartettes. He never spoke of it to us, but those of us who knew him realized that in his life there were three great loves—the sea, music, and his work.

His manner of leaving the hospital was characteristic of the man. One afternoon when he had finished his operation list he took off his gloves, and going over to the Sister said, "Good-bye, Sister; that is my last operation." He shook hands with the others in the theatre, and went down alone in the lift. In the front hall was standing the secretary, Mr. Morris, the only man who knew he had resigned, holding his hat and coat. The hall porter came forward to turn out his light on the board, but he waved him away, stood for a moment looking at his name, and then himself turned off the switch. With one pressure of Morris's hand he left for ever the scene of all his triumphs. He had gone back again to his real love, the sea.

R. D. GILLESPIE, M.D., F.R.C.P.

Dr. R. D. Gillespie, who died on Oct. 30 at the age of 47, was physician for psychological medicine at Guy's Hospital and had identified himself with the York Clinic there. He became civil consultant to the Royal Air Force in September, 1938, entered the R.A.F.V.R. on the outbreak of war, and relinquished his commission as air commodore on account of ill-health last April. At the end of 1941 he went to the United States to report to the American medical profession on the psychological effects of air warfare on the British people, and gave the Salmon Lectures in New York on psychoneuroses from the standpoint of war experience. He lectured also in Canada, and after his return described in this *Journal* (for which he often wrote) a survey by the American Committee for National Morale under the heading "German Psychological Warfare" (April 4, 1942). In the B.M.A. he served as secretary of the Section of Mental Diseases at the Annual Meeting in Edinburgh in 1927 and vice-president of the Section of Neurology and Psychological Medicine in 1937; he was also a member of the Committee on Mental Health set up in 1938.

[*Press Portrait Bureau*

Prof. D. K. Henderson writes:

The untimely death of Robert Dick Gillespie has come to all of us who have been closely associated with him as a shattering blow. There has been removed from our midst a man who was at the very height of his powers, a man who had made many brilliant contributions to psychiatry, and who was loved and respected by all those he had inspired and influenced. At this time it is difficult to collect one's thoughts, so as to do adequate justice to his attainments and to determine the place he had come to occupy, both in this country and abroad, among his medical colleagues. I had known and been associated with him throughout his entire professional career. The bonds between us were very close, and I pay my tribute to his memory and his accomplishments with a sore heart.

He was born and brought up in Glasgow, was educated at Hutcheson's Grammar School and at Glasgow University. Both at School and at the University he greatly distinguished himself, gained many honours, and easily outdistanced the majority of his fellows. After graduating M.B., Ch.B. in 1920, he held appointments as house-physician and house-surgeon with Prof. Stockman and Mr. Edington at the Western Infirmary, Glasgow, and there laid the foundation of a brilliant clinical career. While he was always interested in the problems of general medicine, yet he was more especially attracted to the study of psychiatry and decided to devote himself to it. I can remember as if it were yesterday the day on which he came to see me to ask my advice as to how he might organize his future course of study. He was in the garden of my house in Glasgow and eagerly inquired what books he should read so as to prepare himself for his future work. He was rather puzzled and taken aback when I told him that what I wanted him to do in the first place was to apply himself to the care and management of patients and to base his reading on his practical experience.

I was delighted to appoint him as an assistant physician on the staff of the Glasgow Royal Mental Hospital, Gartnavel. From the first he revelled in his work, his interest grew, he gained the confidence of patients and staff, and showed his ability to formulate his views and express them cogently. I know of no one who could so readily and aptly translate his thoughts to writing; literary expression never seemed to cause him the slightest trouble. It was during that period in July, 1923, that we first collaborated as co-authors and published a paper in the *American Journal of Psychiatry* dealing with the problems of the care and treatment of ex-Service men incapacitated mentally as a result of their war experience. That was a problem very near his heart because he had been bitterly disappointed when he was not considered physically fit for military service. At the end of his clinical training with me he applied for and obtained a McCunn Scholarship in the Department of Physiology in Glasgow University. While there he applied his mind to the problem of fatigue, produced an interesting and original thesis, and was awarded a gold medal for the degree of Doctor of Medicine, Glasgow University.

We had often discussed the advisability of increasing his experience by visiting the United States. To enable him to do so he was awarded a Henderson Research Scholarship and was appointed assistant psychiatrist on the staff of Prof. Adolf Meyer at the Henry Phipps Psychiatric Clinic, Johns Hopkins Hospital, Baltimore. This was an absorbing period in his life. He enjoyed his work there, he made many friends, he was ever grateful for the kindness and hospitality which he received. On his return to Glasgow and while a further appointment was pending I asked him to collaborate with me in writing a *Text-book of Psychiatry* so as to embody and introduce into British psychiatry the psychobiological viewpoint of Adolf Meyer which both of us had found so stimulating. The first edition of our textbook was published in 1927, and ever since that time we have been in the closest association. The success which that book has attained has been due in great measure to Gillespie's enthusiasm, his literary ability, and the apparent ease with which he kept so fully in touch with all the rapid advances in psychiatric work. He had a sure and accurate touch, a fine critical sense, clinical insight to an exceptional degree, and he inspired the confidence of patients and students so that as doctor and teacher he gained the respect and friendship of all associated with him.

In the meantime he was awarded the Pinsent-Darwin research scholarship in mental pathology, University of Cambridge, and was also for a time assistant physician at the Cassel Hospital, Penshurst, Kent. While there he became an ardent admirer of the late T. A. Ross and was influenced considerably by Ross. In 1929 he was called to succeed Sir Maurice Craig as physician for psychological medicine, Guy's Hospital, and lecturer in psychological medicine, Guy's Hospital Medical School. A mere statement of the appointments held, the honours which came to him, and the busy consulting professional life which he led all packed into a short life would have been sufficient to test the endurance of the physically strong among us. Many of us wondered how his slight frame could endure the strain as well as it did, because he never spared himself and responded generously to all the claims which were made upon him. During all this time, in addition to his hospital work and his life as a consultant, he was writing and publishing articles of outstanding merit. His papers, for instance, dealing with hypochondriasis, the association of anxiety states with skin diseases, the psychology and psychopathology of childhood, constitutional psychopathy, and numerous others indicated a fertile mind and easy pen which are given to few. He also found time for more extensive contributions, and his books dealing with *Sleep* (1929), *The Mind in Daily Life* (1933), and his memorable Salmon Lectures delivered in the United States in 1941 on the *Psychological Effects of War* show the breadth of his viewpoint, his interest in social medicine, and his sympathetic understanding of those whom he delighted to help.

During the war years he willingly sacrificed his wide professional and personal interests to serve in the Royal Air Force, and attained the rank of air commodore. I know that his advice was widely sought and approved of and that his judgment was at all times greatly valued. Towards the end of this war period he saw one of his dreams come true—the completion and opening of the York Clinic, Guy's Hospital, the first psychiatric clinic in this country in association with a general hospital. If he had been spared I believe that he would have made this clinic into one of the most valuable training grounds for psychiatry.

Apart from the professional side I would like to take this opportunity to testify to the man himself. Robert Gillespie devoted himself heart and soul to the work which he loved, and in consequence it was not easy to get into touch with his underlying personality. He was handicapped to a considerable extent by his general physique, which was never robust, but yet in his younger days I remember the enthusiasm he showed and the interest he took in captaining the Cricket XI at the Glasgow Royal Mental Hospital. He was a bowler with a deceptive swerve which enabled him to outwit the opposing batsmen and take many wickets. He enjoyed those Saturday afternoon matches and allowed himself to be spontaneous to a degree which many of his later-day colleagues would hardly credit. He had wide cultural interests, was well read in all branches of poetry and prose, and in conversation had a ready and nimble wit which could relieve many an awkward situation. We had many happy times together which it will be a never-failing pleasure to recall, but his passing leaves a blank which it will never be possible to fill. A great man, a loyal friend, and a psychiatrist whose achievements will always do honour to British medicine.

Dr. Frederick William Kerr Tough, who formerly practised at Leith, died in the Western General Hospital, Edinburgh, on Oct. 24. He had studied medicine in Edinburgh, took the Scottish triple qualification in 1901, and was admitted a Fellow of the Royal College of Surgeons of Edinburgh in 1903 after serving as a civil surgeon in the South African War. During the war of 1914–18 Dr. Tough held a commission as major in the R.A.M.C., and later received the Territorial Decoration. On returning to civil life he set up in practice at Leith, where he had been house-surgeon at Leith Hospital. During the second world war he held a commission as major in the Canadian Army, in which one of his two sons is serving. Dr. Tough joined the British Medical Association in 1908 and was a member of the Scottish Committee in 1931–2.

News has been received from Barbados of the death of Dr. Stanley Branch, who had been a member of the B.M.A. for 45 years. He died on Aug. 6, after a very brief illness, at the age of 73. He was fourth in the direct line of a family of medical men, and one of his sons, Dr. Gordon Branch, of the West African Government Service, carries on this tradition to the fifth generation. Stanley Branch received his medical training at the University of Edinburgh, graduated M.B., Ch.B. with honours in 1898, and took the D.T.M. of Liverpool some years later. After holding appointments in St. Lucia, Uganda, and St. Vincent, he was seconded as director under the International Health Board campaign for eradication of hookworm disease in St. Lucia, and held that post until 1924, when he was appointed chief medical officer and health officer for St. Vincent, retiring in 1935. His four sons were all in the Forces during this war, and two are still serving.

Universities and Colleges

UNIVERSITY OF LONDON

Dr. G. A. H. Buttle has been appointed to the University Chair of Pharmacology tenable at the College of the Pharmaceutical Society of Great Britain as from Oct. 1, 1945. For the past six years he has been officer commanding Base Transfusion Unit M.E.F. and 21st Army Group, and latterly consultant for blood transfusion to the War Office.

The title of Reader in Nutritional Science in the University has been conferred on Gladys A. Hartwell, D.Sc., in respect of the post now held by her at King's College of Household and Social Science.

London School of Medicine for Women

Miss Elizabeth Bolton, C.B.E., M.D., B.S., has been elected to the office of President of the London (Royal Free Hospital) School of Medicine for Women on her retirement from the office of Dean. Miss Katharine Lloyd-Williams, M.D., B.S., has been elected Dean in succession to Miss Bolton. The Hon. John Mulholland has been elected Honorary Treasurer of the School in succession to Lord Rennell.

UNIVERSITY OF WALES

The following candidates at the Welsh National School of Medicine have satisfied the examiners at the examination indicated:

M.B., B.CH.—*Hygiene:* T. J. Anthony, A. H. Beynon, Norah C. Curran, D. K. L. Davies, G. E. Davies, G. R. Davies, E. D. Edwards, Gwenllian M Griffith, D. B. Harries, J. M. Hughes, A. S. Jones, Nest Jones, R. L. H. Jones, Mary Lawrence, Bernice G. Lewis, J. M. Lewis, R. Medlicott, Goronwy Owen, Barbara M. Parker, B. F. Richards, Beryl P. Roberts, K. I. Roberts, Jean T Smith, S. L. Stone, W. D. C. Thomas, J. G. Tomkins, D. M. Watkins.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

The Earl of Athlone and Princess Alice visited the Royal College of Surgeons in Lincoln's Inn Fields on Oct. 26, and, after taking luncheon with the President and members of the Council, toured the buildings and inspected plans for rebuilding the damaged parts.

Twelve surgery lectures will be delivered at the College (Lincoln's Inn Fields, W.C.), beginning on Monday, Nov. 12, and ending on Thursday, Dec. 6, at 5 p.m. on each day. Details will be published in the diary column of the *Supplement* week by week. Fellows and Members of the College will be admitted free of charge, but a fee of £2 2s. is charged in the case of others. Tickets may be obtained from the secretary of the College.

The following candidates were successful in the recent Primary Fellowship Examination: D. Aiken, C. E. Baker, E. V. Barling, A. E. Bartolo, J. Borrie, A. Brown, J. Davies, D. H. L. Evans, C. O. Fung-Kee-Fung, R. H. Gardiner, J. L. Gild, G. W. V. Greig, G. F. Homer, J. P. Jackson, R. N. Jones, A. Klidjian, D. W. Lacey, J. W. McNamara, G. E. Mavor, F. T. Moore, T. K. Morgan, G. B. Morris, K. W. Priddis, R. G. Robinson, W. J. W. Sharrard, R. H. Shephard.

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

Prof. Leonard Parsons, M.D., F.R.C.P., F.R.C.O.G., will deliver the sixth William Blair-Bell Memorial Lecture, entitled "Ante-natal Paediatrics," on Friday, Nov. 23, at 5 o'clock in the library of the College House, 58, Queen Anne Street, London, W.

The following have satisfied the examiners and have been awarded the Diploma of the College:

D. W. Bentinck, K. J. R. Cuthbert, Ada I. Date, Ann Donnelly, W. Donovan Mary Downey, Mary M. Essex-Lapresti, Margaret Fitzherbert, S. F. Hans J. O. Harrison, D. W. James, P. S. Jaikaran, G. T. Johnson, J. C. Miller, G. W. Mills, Marjorie B. Morton, D. C. Mundy, Diana J. Myott, J. R. Owen, Ada V. V. Parkes, A. J. Partridge, S. S. F. Pooley, D. P. Jones, O. A. Schmidt, Victoria M. D. N. Shaw, L. S. Stephens, C. E. R. Wood, G. Worden, and J. H. Young.

CONJOINT BOARD IN SCOTLAND

The following candidates, having passed the final examinations, have been admitted L.R.C.P.Ed., L.R.C.S.Ed., L.R.F.P.&S.Glas.:

M. Amin, J. Batchelor, E. J. Bates, G. H.-F. Beith, C. K. Black, R. Burns, W. K. Christopher, S. J. Gelman, J. N. Gould, J. A. Gowans, Hilda Granat, D. Groad, S. Hillman, Ll. B. P. Jones, H. R. Levine, S. G. Loh, D. W. A. McCreadie, I. A. MacGregor, A. B. Mackenzie, A. A. R. Meek, A. S. Mitchell, A. Moselhi, F. A. Murray, W. M. Murray, S. R. Orens, A. C. Parry, A. G. Pollacchi, Margaret MacL. Roake, J. N. Robertson, D. O. Stonewall-Payne, W. R. Taylor, Y. E. Zaki.

L. Nabel, M.D., graduate of a recognized foreign university, was also admitted a Licentiate.

R. B. Logue and J. F. H. Hanson (*Amer. Heart J.*, 1945, **30**, 205) record a case of complete heart-block occurring in the pre-eruptive stage of rubella in a man aged 23. The heart-block was of short duration, and at the end of two weeks the conduction time had returned to normal and the infection had subsided.

The Services

Col. W. E. R. Dimond, C.I.E., O.B.E., I.M.S., V.H.S., Major-Gen. D. V. O'Malley, O.B.E., I.M.S., V.H.S., and Col. R. N. Khosla, O.B.E., I.M.S., have been appointed Honorary Surgeons to the King in succession to Cols. W. C. Spackman, I.M.S.(ret.), and B. C. Ashton, C.B.E., I.M.S. (deceased), and Major-Gen. H. J. M. Cursetjee, C.S.I., D.S.O., I.M.S.(ret.), respectively.

Temp. Acting Surg. Cmdr. A. C. K. Yates, R.N.V.R., has been awarded the D.S.C., and Temp. Surg. Lieut. P. H. Cardew, R.N.V.R., has been mentioned in dispatches for gallantry, skill, and great devotion to duty while serving in one of H.M. ships during the operations performed in collaboration with the U.S. Pacific Fleet in the capture of Okinawa and the Nansei Shoto area, over a period from March 26 to April 20, 1945.

Major-Gen. Sir P. S. Tomlinson, K.B.E., C.B., D.S.O., retired pay, has been appointed Colonel-Commandant in succession to Major-Gen. J. W. West, C.B., C.M.G., C.B.E., retired pay, who has attained the age limit for the appointment.

Major (Temp.) D. L. Charters and Capts. A. L. Cochrane and R. F. K. Webster, R.A.M.C., have been appointed M.B.E. (Military Division) in recognition of gallant and distinguished services while prisoners of war.

Capts. J. H. Patel and V. K. Pillay, I.M.S., have been mentioned in dispatches in recognition of gallant and distinguished services in the field.

Capt. J. G. Lawson, R.A.M.C., has been mentioned in dispatches in recognition of gallant and distinguished services in the field.

It was announced in the *Journal* of Aug. 4 (p. 168) that Major (Temp.) W. M. Macleod, R.A.M.C., and Capt. R. Ramachandra, I.A.M.C., had been mentioned in dispatches in recognition of gallant and distinguished services in Italy. These names should have read Major (Temp.) W. Macleod, R.A.M.C., and Capt. R. R. Rao, I.A.M.C.

Freed in the Far East.—Major H. G. G. Robertson, R.A.M.C.

CASUALTIES IN THE MEDICAL SERVICES

Died.—Capt. James Raymond Dunn, R.A.M.C.

Died at a prisoner-of-war camp in Malaya.—Major John White, I.M.S.

Died at Changi Prisoner-of-war Hospital, Singapore, of beriberi.—Capt. John Diver, R.A.M.C.

Previously reported missing at Arnhem, now officially presumed killed in action.—Capt. Percy Louis, R.A.M.C.

Missing from Sumatra end of Feb., 1942.—Surg. Cmdr. T. C. Stevenson, R.N.V.R.

Medical Notes in Parliament

Christian Science "Nurses"

Mr. LINSTEAD on Oct. 17 moved that the Nurses Regulations (1945) Order made by the Minister of Health under Proviso (b) of Subsection (1) of Section 6 of the Nurses Act, 1943, be annulled. He said that it was an offence for any person not a registered nurse to use the title "nurse" either alone or in combination with any other word. There was a proviso under which the Minister could make regulations authorizing the use by specified persons of specified names or titles containing the word "nurse." Under that proviso the predecessor of the present Minister of Health made a regulation providing that any person recognized by the Church of Christ Scientist as qualified for employment by members of that body might use the title of "Christian Science Nurse." He made no reflection on the Christian Science Church and had seen the authorities of that Church. These explained that before the war trainees were sent to America for the course at a Christian Science school followed by experience in a Christian Science nursing home. Since the war their training had consisted of experience for nearly two years in a Christian Science nursing home. There was no preliminary education, qualification, or examination. There was no statutory register and no oversight of their work. In the case of State-registered nurses in this country there were a high preliminary qualification, certificates of examination, a set course of training, and a State register with disciplinary control by the General Nursing Council. Far less than justice was done to the State-registered nurse by allowing this other group of practitioners to use the name and title of "nurse." When in the Public Health Act, 1936, Section 193 gave an exemption in respect of Christian Science nursing homes this was only done on condition that they were not called nursing homes. He suggested the application of that precedent so that if Christian Science nurses were exempted it should be on condition that they described themselves as "attendants on the sick" and not as "nurses." Mr. MESSER seconded the motion, saying that the General Nursing Council and the Royal College of Nursing both opposed the exemption of Christian Science nurses.

Mr. ALFRED EDWARDS opposed the motion and said the matter had not been slipped through the House. There had been a thorough investigation and a special reference to Christian Scientists which had caused the House to insert the name "Christian Science Nurses." He said these nurses had a thorough training, and a large proportion of them were trained medical nurses who had become Christian Science nurses. They must be recognized like other nurses by a competent body, and there could be no confusion as each must use the title "Christian Science nurse."

Mr. ANEURIN BEVAN said the merits of Christian Science were not at issue. The House was discussing whether in the interests of legal clarity and the nursing profession a people who had not the qualifications which nurses professed should be described as "nurses." The lack of nurses in this country had reached a crisis and was not due entirely to the existence of this regulation. Nevertheless nurses had represented to him that they regarded this exception as one which derogated from the status of their profession. He asked the mover of the motion to withdraw it, and suggested a meeting for the purpose of considering whether a form of words could be found which would be agreeable to all parties. He was bound to say that the concession must come from the advocates of Christian Science, and that if there was to be a modification that modification must be at the expense of those words. After such a discussion he could easily make an amendment to the Regulation. No one would lose his rights and the Regulation could always be annulled. He would take steps to see that organizations which ought to be consulted were consulted. The motion was then withdrawn.

Paper for Book Publishers

Mr. JOHN WILMOT announced on Oct. 22 that the allocation of paper to book publishers generally was being raised as from next month to 65% of their pre-war consumption. He could not say what tonnage of this was used for educational books. The Board of Trade also administered a special reserve to make possible the publication of important books which would not otherwise be produced. A large proportion of this reserve went to educational books.

Infant Mortality in Malta

Mr. HYND stated on Oct. 24 that the infant mortality rate in Malta, which rose during the first years of the war to the maximum figure of 345 per 1,000 in 1942, declined sharply last year to 116 per 1,000—a rate substantially lower than that of the best pre-war year, 1936, when it stood at 190. The rate up to the end of September this year was 154. The lower rate of 1944 was attributed to the fact that there was a substantial increase in the birth rate that year with a large number of first babies. Mr. Hynd suggested that these tended to receive more care and attention from their mothers than their successors. In Malta tinned evaporated milk was reserved exclusively for babies and was rationed. Full-cream milk powder was rationed to children from 19 months to 5 years.

Shortage of Doctors

Mr. AYLES reported on Oct. 25 that the supply of doctors for the urban district of Hayes, Middlesex, was one for every 4,000 inhabitants, and in the near future would be reduced to one for every 5,000 inhabitants. Mr. BEVAN replied that the medical position in this area was difficult. He was in communication with the Central Medical War Committee, which was going into the matter with the local committee. He was doing all he could to increase the supply of doctors for civilian purposes. He hoped there would shortly be a very substantial increase.

Medical "Call-up" and Release

On Oct. 29 Mr. CALLAGHAN asked the Minister of Health to accelerate the rate of demobilization of doctors by calling up newly qualified medical men when they had completed six months' house appointment, by reviewing the cases of those who had been passed medically unfit, and by calling up those medically fit doctors who had remained in civilian life although in the calling-up age limits. Mr. BEVAN said newly qualified medical men were already being called up for the purpose stated. Others up to the age of 40 were being called up to the limited extent required to provide substitutes for certain medical officers whose release was contingent on replacement. The prevailing shortage of doctors in civil practice would not permit a more general recruitment as suggested in the question. Any revision of the standard of medical fitness for the Forces would be a matter for the Ministers in charge of Service Departments.

Compulsory Vaccination

Mr. PETER FREEMAN inquired on Oct. 25 whether the Minister of Health would consider abolishing the compulsory powers of the Vaccination Acts. Mr. BEVAN announced that this was among the matters under examination in connexion with the proposals for a comprehensive health service.

M.O.s in the Army

Mr. LAWSON stated on Oct. 30 that the number of doctors serving in the Army on D Day was 11,328. The number serving at the present time was 10,091. There had been a net reduction of 510 during the month of October.

Future of the Temporarily Registered

Mr. SOMERVILLE HASTINGS on Nov. 1 asked if any decision had been reached as to the cancellation of the temporary registration of alien doctors practising in this country; and whether Mr. Bevan had considered the position of the anti-Nazi Sudeten doctors and others who had no country to which to return. Mr. BEVAN said the Government had considered these matters in connexion with the Bill foreshadowed by the Home Secretary for keeping alive for a transitional period certain Defence Regulations which would otherwise lapse in February.

Navy Demobilization

Mr. W. J. EDWARDS said on Nov. 1 that although a number of doctors in the Royal Navy were anxious to take up civilian practice, Mr. A. V. Alexander could not accept the suggestion that there were doctors in the Navy who were redundant. Doctors would be released as rapidly as possible. Age-and-service group 20 should be reached by the end of this year, and up to Group 30 by the end of June, 1946.

Osteopathy and Further Education Grants

Mr. GEORGE ISAACS disclosed on Nov. 1 that after consultation with Mr. Bevan it has been decided that osteopathy was not a profession for which grants should be given under the Further Education and Training Scheme.

Medical News

Sir John Boyd Orr, M.D., F.R.S., Member of Parliament for the Combined Scottish Universities, was elected Rector of Glasgow University on Oct. 20. He stood as Independent and received 597 votes, the other two candidates, Lord Lovat and Sir Thomas Beecham, receiving 317 and 203.

A meeting of the London Association of the Medical Women's Federation will be held at B.M.A. House (Tavistock Square, W.C.) on Tuesday, Nov. 13, at 8.30 p.m., when Dr. Kathleen Harding will speak on "Physio-psychological Aspects of Pregnancy and Labour."

The Benjamin Ward Richardson Lecture will be delivered by Mr. W. Brennan de Vine, F.R.C.V.S., before the Royal Sanitary Institute (90, Buckingham Palace Road, S.W.) on Wednesday, Nov. 14, at 2.30 p.m. His subject is "The Economic and Public Health Advantages of Centralized Slaughtering."

The Food Education Society (29, Gordon Square, W.C.1) announces that Dr. E. A. Hamilton-Pearson will give a lecture on "Food and Behaviour" at the London School of Hygiene and Tropical Medicine, Keppel Street, on Thursday, Nov. 15, at 3 p.m.

A meeting of the Middlesex County Medical Society will be held at the Central Middlesex County Hospital, Park Royal, on Friday, Nov. 16, at 4.30 p.m.

As part of the 50th anniversary celebrations of the discovery of *x* rays an additional meeting is to be held to-day (Friday, Nov. 9) at 8 p.m. at the Royal College of Surgeons, Lincoln's Inn Fields, W.C., with Sir Alfred Webb-Johnson, Bt., in the chair. Prof. Sidney Russ, D.Sc., honorary secretary of the British *X*-ray and Radium Protection Committee, will speak on dangers associated with the use of *x* rays, and Prof. H. J. Muller, D.Sc., of Amherst College, Massachusetts, on genetic effects in relation to *x* rays and other ionizing radiations.

Alderman Charles Key, Parliamentary Secretary to the Ministry of Health, said on Oct. 31, in opening the Nursing Exhibition at Liverpool, that the Minister of Health is giving his close personal attention to the supply of nurses and midwives and is expecting in the near future to make a statement about the whole position.

The Nutrition Society announces a whole-day conference on the training, qualifications, and functions of dietitians to be held at the London School of Hygiene and Tropical Medicine, Keppel Street, W.C., on Saturday, Nov. 17, beginning at 11 a.m. Papers will be delivered by Prof. S. J. Cowell and Miss R. Pybus, The Training of Dietitians: the Current Position; (a) Miss M. C. Broatch and (b) Lieut.-Col. A. N. Childs, The Function of Dietitians and their Role for the Future—(a) General, and (b) with Special Reference to U.S.A. and Canada; (a) Dr. C. F. Brockington, (b) Mr. F. Le Gros Clark, (c) Miss F. C. R. Brown, and (d) Miss J. I. Mills, Scope of Work of Dietitians in Specialized Groups—(a) Public Health, (b) Schools, (c) Industry, and (d) Hospitals. Non-members wishing to attend should apply to a member of the Society for a ticket of admission. Further details may be obtained from the Honorary Secretary, Dr. L. J. Harris, Nutritional Laboratory, Milton Road, Cambridge.

The Medical Research Council has appointed the following to be members of its Industrial Health Research Board until Aug. 31, 1948: Prof. F. C. Bartlett (chairman), Dr. A. N. Drury, Prof. T. Ferguson, Lord Forrester of Corstorphine, Prof. A. Bradford Hill, Dr. Donald Hunter, Prof. Esther M. Killick, Prof. R. E. Lane, Prof. J. M. Mackintosh, Dr. E. R. A. Merewether, Prof. J. A. Ryle, and Mr. J. L. Smyth. (Dr. R. S. F. Schilling, seconded to the Council's headquarters staff from the Factory Department of the Ministry of Labour and National Service, continues to be secretary of the Board.)

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* whooping-cough, acute pneumonia, and diphtheria increased in prevalence. The notifications rose in number by 117, 103, and 39, while those for scarlet fever fell by 81.

The diminution in scarlet fever was principally in the northern counties. The largest variations in whooping-cough were a rise in Southampton of 54 cases, and a fall in Warwickshire of 30. The increase in the incidence of diphtheria was contributed by only a few counties; the largest rises over last week's totals were 13 cases in Surrey, 12 in Warwickshire, and 10 in Gloucestershire.

The only fresh outbreak of dysentery was in Hertfordshire, Harpenden U.D. 12 cases. The other large returns were London 50, Lancashire 40, Surrey 32, Glamorganshire 17, Kent 15, Middlesex 14, Warwickshire 13.

A case of smallpox has been reported in London. The patient was a soldier returned from abroad.

In *Scotland* the only variation of note in the returns was an increase of 34 in the incidence of scarlet fever. The notifications of diphtheria in Glasgow increased by 16. The largest returns of dysentery were Glasgow 40, and Edinburgh 19.

In *Eire* the notifications of diphtheria were 20 fewer, but the incidence of measles rose by 47, and of diarrhoea and enteritis by 27. Measles was mainly confined to Dublin C.B. 51, and Dublin North U.D. 34, the remaining 7 cases appearing in six registration areas. Sixty-one cases of diarrhoea and enteritis were notified in Dublin C.B.

Diphtheria

A study of the recent returns of diphtheria suggests that a large continuous reduction in incidence, which seemed likely from the trend of the disease during the first months of the year, will probably not occur. Since 1942 the successive seasonal rises have decreased and the autumn level has been lower than that of the preceding spring rise, but this may not characterize the returns of this year. The following table gives a comparison of the returns for the most recent period and the first weeks of the year with the corresponding periods of the preceding year.

Weeks	Notifications 1942	1943	1944	1945
1–13	11,658	10,799	9,005	6,061
29–42	10,988	8,952	6,873	6,206

The incidence of diphtheria may be reverting to the size of that of a year or two ago, although it is too early to state whether the increase has any real significance or is just a chance occurrence. The present trend is disappointing.

Week Ending October 27

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,754, whooping-cough 1,029, diphtheria 576, measles 422, acute pneumonia 547, cerebrospinal fever 35, dysentery 247, paratyphoid 5, poliomyelitis 27, typhoid 12.

No. 42

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Oct. 20.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease. are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1945					1944 (Corresponding Week)

Rate per 1,000 total births (including stillborn)			31					23		

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to movements of population, birth and death rates for Northern Ireland are still not available.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Aitiology Westcent, London.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London.*

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Westcent, London.*

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Bed-sores

Q.—*What principle underlies the use of spirit in the prophylaxis and treatment of bed-sores? What are the correct prophylaxis and treatment of bed-sores in view of the fact that any spirit is detrimental to skin lesions?*

A.—When a part of the body is subject to recurrent or prolonged pressure it is essential to keep the area quite clean. This is done at stated intervals by washing it carefully with soap and water. After washing and drying the part with a smooth towel it is customary to apply spirit for three reasons: first, to complete the drying process; secondly, to harden the skin and make it more resistant to pressure; and, thirdly, with the hope that the alcohol may exert an antiseptic action on any organisms in the vicinity. Some authorities do not believe that its action in any of these respects justifies its use, and prefer to place their reliance in the prevention of bed-sores upon a complete relief of pressure on the threatened area.

The treatment of an actual sore includes relief of pressure, the application of antiseptic and astringent solutions, or the use of adhesive strapping across the affected part. For the various substances applied the questioner should consult a textbook on nursing.

Bite of Culex molestus

Q.—*Is there any antivenene for the bite of Culex molestus? A patient has lost 18 days' work this year as a result of successive bites of this insect. Within two hours of the bite there is a local erythema and induration about 2 in. in diameter, but by 24 hours there is gross oedema of the part, usually the hand and forearm, with lymphangitis and lymphadenitis in upper arm and axilla. Sulphonamides, adrenaline injections, and ephedrine are without effect. The condition subsides in 3 to 5 days, but during this period the man cannot work.*

A.—Unfortunately there is no antivenene for protection against the irritant effects of mosquito-bites. Normally people become gradually immune to the severe after-effects; for example, people going to live in the Tropics are sometimes badly affected at first but gradually become more or less indifferent to the actual bites. The best course to be adopted for the patient in question is to use a repellent while he is exposed to the bites (e.g., dimethyl phthalate). If possible the breeding-site of the mosquito should be traced and dealt with.

"Soma" and "Psyche"

Q.—*Is there any drug known at present (apart from the morphine, cocaine, cannabis, benzedrine, and mescaline compounds) which has the specific property of producing euphoria in the human subject? Such an agent, if free from the undesirable side-effects associated with the above-mentioned compounds, might have important applications in the therapy of some forms of mental disorder. Has any research on this subject been carried out or published in recent years?*

A.—The specific euphoric effect of these drugs is very unreliable. All of them, with the exception of benzedrine, produce a clouding of consciousness which is found by some people agreeable (more frequently so with heroin and cocaine) but by others unpleasant. For the most part they produce euphoria in the same way as does alcohol—i.e., by narcotizing the cortex and removing tensions and inhibitions. The euphoria produced by benzedrine does not depend on this mechanism, but is in most persons very slight. It was first introduced to psychiatry by Guttmann and Peoples for the treatment of depressive states, but has been found of comparatively little value for that purpose; its value in the treatment of narcolepsy, enuresis, certain syndromes found to accompany cerebral dysrhythmia, etc., does not depend on any euphoria produced by it.

A drug, such as Aldous Huxley's "soma"—i.e., almost non-toxic but producing a high degree of euphoria—could have enormous social consequences, but would be unlikely to have more than palliative value in the treatment of mental disorder. The treatment of such conditions must depend in the first place on the correction of a dysfunction or the remedy of a deficiency.

Vitamin B in Dried Yeast

Q.—*Do the spores of the yeast organisms persist as such in tablets of dried yeast, and if so, given suitable conditions, do they grow? Are the amounts of the vitamin B complex fairly constant in the various dried-yeast tablets on the market? In other words, if one prescribes a 5-grain yeast tablet, is one prescribing a given dosage of the B vitamins?*

A.—Yeasts do not normally multiply by spores at all, but by the budding of vegetative cells. Dried yeast preparations may contain sufficient viable cells for multiplication to begin if they are moistened and allowed to stay in the presence of a suitable liquid medium. A few spores may be present, but they are of little importance for purposes of further culture. The extent to which sufficient viable vegetative cells will be present must naturally depend on many conditions, including the degree of desiccation to which the product has been submitted and the length of time that it has remained dry, as well as, probably, temperature of storage. In general, however, it is better not to regard dried yeast as a suitable source of *living* yeast cells, but rather as a subsidiary food reasonably rich in certain essential nutrients.

The amounts of the various members of the vitamin B complex present even in yeast of one strain are likely to vary somewhat, and the variation will be *pro tanto* greater in harvests from mixed strains. Certain manufacturers of proprietary dried yeast "standardize" for vitamin B_1, by assay and suitable blending of various batches. This must inevitably mean that the other members of the complex, of which riboflavin and nicotinic acid are probably the most important in human nutrition, have simply to "take their chance." Dried yeast should in any event not be used as a standardized source of individual vitamins, but rather as a foodstuff rich in certain nutrients the concentration of which, in a reputable brand, is unlikely to fall below a certain fairly high figure.

Diphtheria Prophylaxis

Q.—*Is it safe to give, without a preliminary Schick test, T.A.F. to a child of 5 years previously immunized at 1 year with A.P.T.? In a busy practice the Schick test takes more time than can be afforded.*

A.—It would be perfectly "safe" to give either T.A.F. or a further "boosting" dose of A.P.T. in these circumstances. The latter would be preferable, since it immunizes better, and children of this age rarely react badly to it. The question does not convey the reason for supposing that such an injection might have harmful effects: if it is meant that some form of sensitization might have occurred, the answer is that the amount of protein in the materials is too small for any such effect.

Antispasmodics

Q.—*Trasentin is said to be a good antispasmodic. Would its continued use (say, 1 tablet t.d.s.) be harmful in any way? (I have in mind the type of patient, described by Alvarez, with a super-hypertonic stomach and spasmodic contractions in the colon.) Incidentally, would it be calculated to relax vascular spasms?*

A.—No reports have been seen of harmful effects from the prolonged use of trasentin. Trasentin is a synthetic analogue of atropine, and it is characteristic of this group of alkaloids that they are relatively free from toxic effects. Although trasentin is described as having a papaverine-like action in relaxing the smooth muscle of the intestine, there is no evidence that it has a similar action on the blood vessels. Atropine itself only dilates the blood vessels when given in toxic doses, and one would not expect trasentin to be superior in this respect.

Osgood-Schlatter's Disease

Q.—*A girl aged 13 has had Osgood-Schlatter's disease for about 12 months. She is training to be a ballet dancer, but is handicapped by the pain in both tibial tubercles. She has been told to rest, but this will interfere with her career. Are there any other methods of treatment, and what is the prognosis if she continues to dance?*

A.—Osgood-Schlatter's disease is comparable with adolescent coxa vara. Both are lesions in which various degrees of epiphysial separation occur as the result of repeated violence or continual static stress in association with metaphysial chondritis, the latter in the more extreme forms being due to constitutional and metabolic disturbances. There is some similarity to certain types of stress fracture. In Osgood-Schlatter's disease the element of extension stress must be realized, and immobilization of the knee in almost complete extension for six weeks or so is desirable, followed by rest from dancing or running for a further two months. In a young dancer failure to treat it seriously will almost certainly delay recovery indefinitely. Various other measures have been recommended, such as drilling, but conservative measures are sufficient. Rest for the knees at the age of 13 may interfere temporarily, but unimportantly, with her career: a persistently painful tibial tubercle may ruin it.

Causes of Deaf-mutism

Q.—*What are the causes of deaf-mutism—other than the accepted theory of the mother contracting rubella while pregnant? Is it possible that large doses of quinine taken in an attempt to produce abortion in early pregnancy would be responsible for this condition?*

A.—There is no evidence that quinine taken during pregnancy is a cause of deaf-mutism. It is in fact unlikely that any external factors operating before birth can be responsible for more than a small proportion of instances. Deaf-mutism may be hereditary or acquired; an estimate of 50% of cases falling into either category may, perhaps, prove to be not very wide of the mark. Any disease which destroys the hearing sufficiently early in life may be the causal factor—for example, scarlet fever, meningitis, or syphilis.

Simple recessive inheritance accounts for at least the very large majority of the hereditary cases. The criteria by which the type of transmission may be recognized are well exemplified: (*a*) The majority of deaf-mutes are the offspring of normal parents. (*b*) Frequently more than one child in the sibship is affected. (*c*) Consanguineous marriages among the parents are commoner than in the general population. (*d*) Affected persons who marry each other have affected children only. This is the usual finding in deaf-mutism. Certain instances in which the offspring were all normal are to be explained either by the condition being an acquired one in one or both parents (as has sometimes been observed), or it may be that more than one recessive gene may give rise to deaf-mutism—which would also lead to apparent exceptions.

Deaf-mutism is sometimes encountered as part of more complex syndromes. For example, its occurrence in association with retinitis pigmentosa serves to distinguish one variety of that condition. This syndrome, like uncomplicated deaf-mutism, also depends upon a recessive gene.

Maturing of Threadworms

Q.—*How long do threadworms take to mature, and what interval must elapse after the appearance of the last worm to consider the cure certain?*

A.—The period of development, from the ingestion of the infective egg to the time of oviposition by the gravid female, is given by different authorities as from fifteen days to two months; probably it rarely exceeds one month. It must be remembered that under suitable conditions the ova may remain alive and infective for periods up to five days, and possibly longer. In such circumstances the patient may become infected from his own fomites, even when not in contact with infected neighbours.

Safety of Butter and Cheese

Q.—*There is much talk at present of the danger of allowing children to drink unboiled milk. Is there any similar danger in allowing them to eat (a) farm butter, (b) National butter, (c) cheese? I believe that the milk used in making farm butter is not generally heat-treated in any way, but I am not aware by what process National butter and cheese are manufactured.*

A.—For general interest the answer to this question may be slightly expanded: At present about 94% of butter distributed in this country is imported, 4% is home-produced in factories, and 2% is home-produced on farms. Practically all imported and factory butter is made from pasteurized or otherwise heat-treated cream, and may therefore be regarded as free from living tubercle bacilli or other pathogenic bacteria. Farm butter is made from raw cream and must be considered potentially dangerous. Most pathogenic organisms, however, including the tubercle bacillus, die out fairly rapidly in butter, owing partly, perhaps, to the amount of acid produced. Though it would be unjustifiable to dogmatize, it is probably fair to say that the danger of contracting disease from farm butter is confined mainly to the fortnight following its manufacture. It may be added that nearly all farm butter is consumed in farming households, and that very little finds its way to the open market.

Of the cheese consumed in this country, 92% is imported, 7% is home-produced in factories, and 1% is home-produced on farms. Probably not less than 60% of imported and factory cheese is made from heat-treated milk; the remainder, including farm cheese, is made from raw milk. Before the war most "hard" cheeses (Cheddar and Cheshire types) were ripened for several months before being offered for sale—a process that led to the death of all pathogenic bacteria; but, as pointed out in the *Journal* (June 12, 1943, p. 730), it became common during the war to distribute imported cheese from the United States and Canada which had had no adequate period of ripening. That unripened cheese may cause disease is illustrated by the occurrence in Canada during the past few years of three or four outbreaks of typhoid fever traced to this source. These outbreaks were caused by cheese that had been consumed within two or three weeks or so of manufacture, and it is doubtful whether the cheese would have proved infective if it had been kept for longer. Between manufacture in America and distribution in this country several weeks elapse, and it is possible, therefore, since pathogenic bacteria are known to die out almost completely within two months in cheese kept at 50° F. or over, that very few, if any, of these organisms are alive by the time the cheese reaches the consumer in this country. There is not enough evidence to assess accurately the risk of disease being carried by cheese made from raw milk, but, considering the relatively small quantities that are eaten at a time, the danger of infection resulting from the consumption of factory-produced cheese must be very small. On the other hand, cheese produced on farms in this country—particularly if it is of the "soft" or cream cheese variety—should be treated with caution, since such cheese is often eaten within a week or so of production. Children had better avoid it altogether.

LETTERS, NOTES, ETC.

Pasteur Institute during the Occupation

Dr. Ronald MacKeith (chairman, Medical Committee, Scientific Film Association) writes: I read with interest the leading article on Pasteur (Sept. 29, p. 429). Your readers may like to know that the French Office of Information (54, Queen Anne Street, W.1) have just received from France a film made during the occupation, illustrating the work of the Pasteur Institute. *L' Institut Pasteur* contains also some historical matter, and although designed for the general public it will be of real interest to a medical audience. It is a sound film, available 16 or 35 mm., with a French commentary. The running time is 20 minutes.

Sprouting Legumes

J. A. N. writes: Your editorial note on sprouting legumes suggests that it might be of interest to recall the earliest mention of this expedient that I have so far come across. Capt. T. Forrest in his *Voyage from Calcutta to the Mergui Archipelago* (published in 1792) closes the book with "Thoughts on the Best Mode of Preserving Sea Provisions or of Victualling Ships in Warm Climates." In this chapter he mentions "that great antiscorbutic salted limes, lemons or oranges"; he also relates (p. 135) that he sprouted his peas, a trick which he says he learnt from the Malays. I wonder if this is still practised in Malaya. Did Fürst or Chick and Delf know where and how the idea came to be revived?

Books for Polish Doctors

The Polish Medical Association in the British Empire is appealing for gifts of medical and scientific books to reconstruct the libraries in Poland that have been destroyed in the war and to replace books that were confiscated or stolen during the German occupation. In the efforts now being made to train young people for the work of reconstruction the greatest problem is the lack of books. In the field of medicine teachers badly need textbooks for their students, and books, reference books, and periodicals to bring their own knowledge abreast of the scientific progress made in recent years. Doctors in Great Britain are invited to offer to the Polish profession any medical or scientific books or periodicals they can spare; the language may be English, German, or French. Their help will be greatly appreciated. Books and periodicals may be sent to the Secretary of the British Medical Association at B.M.A. House, Tavistock Square, W.C.1. Correspondence on the subject should be addressed to Dr. B. Jedlewski, 43, Eaton Place, S.W.1.

Corrigenda

Owing to delay in the post the corrected proof of the letter on significance of the erythrocyte sedimentation rate by Drs. D. G. McIntosh and D. M. Keay was received after we had gone to press with the issue dated Oct. 27. On page 584 in the fourth numbered paragraph (*Disregard of Physiological Variations*), line 20, the figures should be 13 of 53, instead of 18 of 55. In the table the reference to Abeles and Pinner should read 86 in the second column, instead of 91.

Dr. K. R. Ogilvie wishes to correct an error in his letter on Ludwig's angina published on Nov. 3. In column 1 of page 623 when describing Case II he wrote "tracheotomy tube" by mistake for "endotracheal tube."

By an error, the name of Prof. J. R. Marrack, one of the signatories of the Memorandum on Training and Qualifications of Dietitians, was omitted from the second sentence of the introductory paragraph of the report published in the *Journal* of Nov. 3 (p. 617). The sentence should have read: "The committee has summarized its findings in the subjoined memorandum, but two of its members (Miss M. Grant and J. R. Marrack) have dissented from paragraph 1 (concerning membership of the British Dietetic Association and registration as medical auxiliaries)."

THERAPEUTIC EFFECT OF INDUCED JAUNDICE IN RHEUMATOID ARTHRITIS

BY

FRANCES GARDNER,* M.D., M.R.C.P. **ALICE STEWART, M.D., M.R.C.P.**

(Nuffield Department of Clinical Medicine, Radcliffe Infirmary, Oxford)

AND

F. O. MacCALLUM, M.D., B.Sc.Toronto

(Wellcome Research Institution, N.W.1)

It is an old observation that when patients suffering from rheumatoid arthritis develop jaundice there may be a remarkable improvement in the condition of the joints (Still, 1897; Wishart, 1903; Hench, 1938), but until jaundice could be induced without undue risk to life it was difficult to study this phenomenon systematically. Attempts to imitate the condition by the intravenous injection of bile salts and bilirubin (Thompson and Wyatt, 1938) failed to reproduce the effects observed in the naturally occurring disease, but in 1944 MacCallum and Bradley reported remissions in 6 patients who had been successfully inoculated with material from cases of infective hepatitis. Since then we have induced infective hepatitis and homologous serum jaundice in 29 patients. The present paper contains a report of the results obtained in these patients and in three of the patients referred to by MacCallum and Bradley who were under our care in Oxford.

Jaundice is not easy to induce and is not entirely without risk. Before accepting volunteers care was taken to explain to them the experimental nature of the treatment and the risks involved. Emphasis was laid on the uncertainty of the benefit to be derived, and it is perhaps some indication of the courage and the present hopeless state of the rheumatoid subject that large numbers of patients were anxious to take part in the experiment. The work was carried out at several different centres, and, as it was impossible to foretell which patients would develop jaundice, only the simplest type of pilot investigation was undertaken. Our intention was to discover whether remissions in the joint condition occurred often enough to justify a more detailed study of the phenomenon at a later date.

From time to time batches of dried serum have produced jaundice when used for transfusion purposes. A small amount of such serum injected subcutaneously will produce jaundice in a high percentage of cases (Bradley, Loutit, and Maunsell, 1944). This method of inducing jaundice could have been used for all cases, but when planning the experiment it appeared to have two disadvantages. The first was the long incubation period, averaging nearly 100 days. The second was the fact that jaundice is sometimes unduly severe when the disease is induced in this way. At first, therefore, we attempted to transmit the disease with material from cases of infective hepatitis and, in order to discover the route with the shortest incubation period, we inoculated patients by the nasopharyngeal route as well as by parenteral injection. Unfortunately many of these attempts proved unsuccessful and only a small percentage of the patients developed jaundice. Later in the experiment we used icterogenic serum and induced jaundice in a high proportion of cases. The severity of the hepatitis produced in this way was no greater than in the previous cases, and the effect on the rheumatoid arthritis was essentially similar. Details of these experiments, in so far as they concern the transmissibility of infective hepatitis and homologous serum jaundice, will be discussed elsewhere.

All the patients had received other forms of treatment in the past. Several had responded to gold but had lately either become insensitive to this or had developed toxic reactions. Others had had spa treatment, vaccines, salicylates, or physiotherapy. So far as was possible only patients who had recently failed to obtain benefit from these treatments were included in the present investigation. At first no patient who had received gold injections during the previous six months was allowed to take part, but later this period was reduced to three months. After inoculation patients continued to have physiotherapy and aspirin, but no other treatment was allowed.

Details of the Investigation

The patients were all suffering from polyarticular arthritis of the rheumatoid type. They were arranged in four groups according to the classification of rheumatoid arthritis suggested by Sclater in 1943:—Group I: Periarticular swelling and stiffness, but only slight limitation of movement. Group II: Periarticular swelling and more marked limitation of movement than in Group I, but no evidence of ankylosis; still capable of employment. Group III: Fixation of joints and flexion deformities; either inability or great difficulty in continuing employment. Group IV: Gross deformities and severely crippled; usually bedridden and unable to walk.

Only 32 of the 312 patients inoculated developed jaundice. Ten were in Group I, five in Group II, eleven in Group III, and six in Group IV. Their ages ranged from 22 to 61 years, and there were 24 females and 7 males. The severity of the hepatitis induced was variable. In the mildest cases jaundice lasted only one week, and in the most severe it persisted for 45 days. The disease ran its usual course, and in most cases a few days of anorexia, vomiting, and low-grade pyrexia preceded the appearance of jaundice and biliuria. The liver became enlarged and tender in most cases, and in two the spleen was palpable. Persistent vomiting was a troublesome complication in some of the severely ill patients; fleeting erythematous rashes were seen and petechial haemorrhages occasionally occurred. Maximum serum bilirubin values ranged from 2 to 19 mg. per 100 c.cm. One patient had a recurrence of jaundice two months after her first attack; otherwise convalescence was uneventful.

All the patients who were inoculated were kept under observation for at least six months. During this time occasional minor fluctuations in the arthritis occurred among the subjects who failed to develop jaundice, and two patients had a genuine remission. This was ascribed by the patients to the inoculation they had received, but there was in fact no evidence to support this view. One remission may have been due to a recent course of gold injections. The other patient began to improve immediately after she received her inoculation.

In the cases successfully inoculated an interval which varied from 27 to 131 days elapsed between the day the inoculation was given and the day jaundice appeared. During the incubation period there was no radical change in the rheumatic condition, but with the appearance of jaundice dramatic improvement was noticed in many of the patients. In one instance this improvement began three days before jaundice was detected, in 8 it started on the first day, in 13 within the first ten days of jaundice, and in 3 after the first two weeks. One patient was exceptional in that all the affected joints became more painful during the attack of hepatitis, but immediately after recovery all pain and stiffness disappeared. She has remained free from symptoms since—a period of over three months.

---

* With a grant from the Medical Research Council.

The remissions, which were temporary, have been classified as follows:

A. *Complete.*—Ten patients became completely free from pain in all joints. Periarticular swelling disappeared and free movement was restored except where this was limited by permanent deformity.

B. *Marked Improvement.*—Eight patients became free from pain in many but not all affected joints. Periarticular swelling diminished and there was greatly increased mobility.

C. *Slight Improvement.*—Seven patients obtained some relief of pain and swelling with increased movement, but this was less marked than in Group B.

D. *No Change.*—In 7 patients the joint condition was unaltered.

In Groups A and B the amelioration in the joint condition was remarkable. Disappearance of pain and swelling was quickly followed by increase of power and range of movement in the affected joints. These changes were observed in both the larger and the smaller joints, but they were perhaps most pronounced in the fingers. One patient whose fingers had been locked for two years was able to move them on the third day of jaundice. Thereafter the swelling rapidly subsided, and by the sixth day she had full and painless movement of her fingers. Three other patients were able to wear their wedding-rings for the first time for several years. In Group C the joint changes were less obvious, but there was considerable subjective improvement. Two patients who had had constant pain and were unable to turn over in bed found that within a week of the onset of jaundice they could move freely and painlessly, and thereafter their general condition improved considerably. Details of the 32 cases are given in the accompanying Table.

The following case histories illustrate the changes observed.

Case I (Sclater Group II; Type A Remission)

Housewife aged 42. 1936:—Pain and swelling in ankles and shoulders. 1940:—All joints affected. Unable to work. Course of bee venom injections without improvement. 1943–4:—Gold therapy, with gradual improvement. Able to do light housework.

Dec. 20, 1944.—All joints painful. Swollen interphalangeal joints. Grip weak. Extension of elbows limited by 50°. Knees swollen. Flexion to 45° only. Ankles swollen; only 5–10° of movement. E.S.R., 12 mm. Serum bilirubin, 0.25 mg. per 100 c.cm. Inoculation with nasal washings from case of homologous serum jaundice.

March 30, 1945.—Anorexia, vomiting, icteric sclera. Joint condition unchanged.

April 8.—Appetite improved. Joints less painful. No swelling of fingers; grip. Elbows—full extension. Knees still painful; flexion to 80°. Ankles—no swelling; full range of movement. E.S.R., 10 mm. Serum bilirubin, 18 mg. per 100 c.cm.

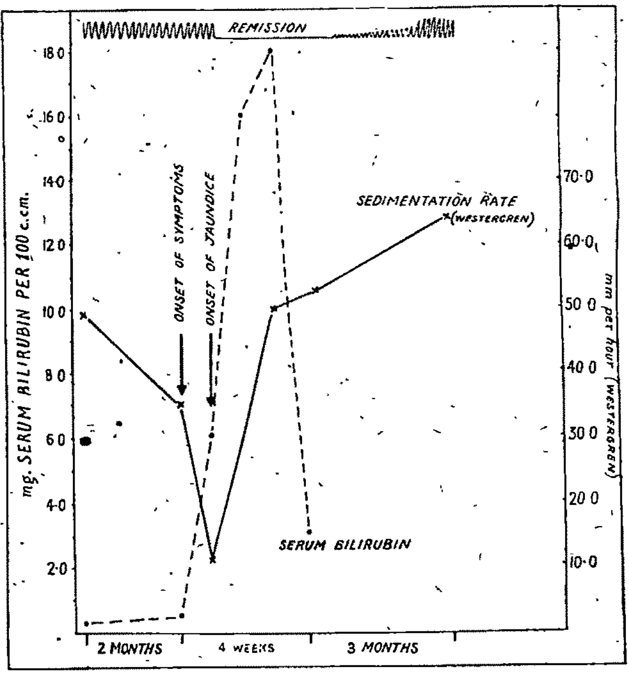
April 12.—All joints free from pain and swelling. Knee flexion to 90°. Other joints—full range of movement.

June 18.—Well. Able to do all her own housework. Full painless movement of all joints.

July 16.—Recurrence of pain, with swelling and limitation of movement in one finger of left hand; otherwise all joints remain satisfactory. E.S.R., 15 mm.

Case II (Sclater Group III; Type A Remission)

Housewife aged 47. 1940:—Pain and swelling in feet and hands. 1942:—Exacerbation, with involvement of all joints. Temporary remission following gold. Two further courses of gold, with no improvement. Unable to work for three years.



Case II. Diagram to show the relation between the E.S.R., serum bilirubin, and the temporary remission of the rheumatoid arthritis.

Nov. 7, 1944.—Ambulance case. Walks a few steps with difficulty. Gross flexion deformity of hands; swollen wrists, minimal movement of these joints. Feet swollen and painful. Moderate limitation of movement at shoulders, elbows, and knees. Right knee swollen. E.S.R., 49 mm. in 1 hour. Plasma bilirubin, 0.2 mg. per 100 c.cm. 0.5 c.cm. icterogenic serum given by subcutaneous injection.

Dec. 28.—Severe backache. Nausea. Non-irritating rash on arms and legs. Joint condition unchanged. E.S.R., 35 mm. Bilirubin, 0.5 mg. per 100 c.cm.

Jan. 2, 1945.—Vomiting, giddiness, and abdominal pain. Rash fading. Jaundiced sclera. Liver palpable and tender. Movements in right hand improved. Onset of pain in temporo-mandibular joints. Other joints i.s.q. E.S.R., 11 mm. Bilirubin, 6 mg. per 100 c.cm.

Jan. 5.—Lying comfortably in bed. No nausea. Appetite good. Jaundiced. Considerable relief of pain in all joints except right knee and jaw. Increased range of movement in fingers. No improvement of wrist movements. Bilirubin, 16 mg. per 100 c.cm.

Jan. 16.—Feels well. Still jaundiced. No pain except in right knee. Moves easily in bed. Full range of movement in hands and wrists. No visible swelling in any joint. E.S.R., 50 mm. Bilirubin, 18 mg. per 100 c.cm.

Jan. 23.—No symptoms. Jaundice almost faded. Complete relief of pain. Walking freely and using hands. Full range of movement in all joints. E.S.R., 52 mm. Bilirubin, 3 mg. per 100 c.cm.

Feb. 23.—Home doing housework for 5 weeks. Slight recurrence of pain in finger-joints 3 weeks ago. Since then pains in neck and left arm. Still free from pain in legs and shoulders. E.S.R., 52 mm.

April 25.—Steady deterioration in joint condition during last 2 months. Now no better than before jaundice. E.S.R., 64 mm.

Case III (Sclater Group IV; Type C Remission)

Ex-coalminer aged 56. 1932:—Pain and stiffness in the hands, 1940:—All joints affected; had to give up employment. 1943:—Gold therapy; discontinued because of generalized oedema.

Nov. 7, 1944.—Constant pain, unable to move in bed. Wrists ankylosed and painful. Wasting of interosseus muscles; swelling and limitation of flexion of finger-joints. Knees and ankles painful; full range of movement but great loss of power. E.S.R., 30 mm. Serum bilirubin, 0.2 mg. per 100 c.cm. Inoculation with 0.5 c.cm. icterogenic serum.

Jan. 13, 1945.—Nausea, vomiting. *Jan. 18.*—Jaundiced; joints less painful.

Jan. 22.—Anorexia. Deeply jaundiced. Liver enlarged. Moving freely in bed. All joints except feet free from pain. Range of movement and swelling of joints unaltered.

Feb. 8.—Up and about. Eating well. Wrists painless. Occasional pain in feet.

April 28.—Subjectively very well. Joint pain and swelling gradually returning. E.S.R., 37 mm.

The degree of improvement seemed to be influenced more by the duration of the rheumatoid arthritis than by the severity of the jaundice, but the number of cases is small and the difference is not statistically significant. Twelve patients had had the disease for less than 5 years. Of these, 6 had complete remissions, 4 had some relief, and only 2 failed to improve. Twenty patients had suffered from rheumatoid arthritis for over 5 years. Of these only 4 had complete remissions, 11 had some improvement, and 5 obtained no relief.

Twelve patients developed a maximum serum bilirubin of over 9 mg. per 100 c.cm. Of these, 4 had complete and 6 partial remissions, while 2 failed to improve. Twenty patients never had more than 8 mg. per 100 c.cm. serum bilirubin. Of these, 6 had complete and 9 had partial remissions, while 5 obtained no relief. There is no statistical difference between these results.

In most cases the period of optimal improvement was short, but it was often several months before the joints reverted to their pre-icteric condition. In Group A (complete remission) the average period of complete freedom from pain was 44 days, the longest time being 93 and the shortest only 7 days. In the cases with an incomplete remission the period of greatest relief averaged 41 days, the longest period being 154 and the shortest 7 days.

The Erythrocyte Sedimentation Rate

In rheumatoid arthritis the E.S.R. provides an index of the activity or quiescence of the disease process. In infective hepatitis it has been shown that the E.S.R. is higher in the pre- and post-icteric stages of the disease than it is when jaundice is present. It is therefore probable that when a patient with rheumatoid arthritis develops infective hepatitis the E.S.R. no longer reflects the joint condition alone.

Changes in E.S.R. were observed in some of our cases. In 14 there was an abrupt fall shortly after the appearance of jaundice, in 7 there was no change, and in 4 the E.S.R. was raised. Two or more months after the recovery the E.S.R. had fallen below the pre-icteric level in 5 cases, in 7 it was unchanged, and in 15 it was well above its original value. These alterations were not apparently related to changes in the clinical status of the rheumatoid arthritis. The early fall occurred in patients who failed to benefit from the intercurrent jaundice as well as in those who obtained relief. At the time of the late rise in sedimentation rate only a few of the patients had relapsed; in 6 cases the joints were still much better than they had been before jaundice was induced, in 5 they were essentially unchanged, and in 4 they were worse than they had been before inoculation.

Somewhat similar changes in E.S.R. have been observed in tuberculous patients who develop infective hepatitis. Penman (1943) recorded an epidemic in a sanatorium in which all the patients showed a remarkable fall in E.S.R. while jaundiced. In his cases the E.S.R. had returned to its pre-icteric value within a month of recovery from the intercurrent infection.

Discussion

The natural course of rheumatoid arthritis is so variable that it is difficult to assess the value of any remedy which produces only temporary benefit. But the fact that only two of the patients who failed to develop jaundice had a spontaneous remission during the period of observation, whereas 10 of the 32 who were successfully inoculated became completely free from pain and 15 showed some improvement, suggests that the two events are related. Some change which occurs during the course of infective hepatitis must exert a favourable effect on the joint condition, but as to the nature of this change we have as yet no clue.

Hench (1938), who analysed all the cases in the literature and observed this phenomenon in many of his own patients, came to the conclusion that the improvement obtained was related to the intensity of the jaundice, and that below a threshold value of 8 mg. per 100 c.cm. serum bilirubin little improvement was to be expected. Our results do not confirm this view, and the fact that Thompson and Wyatt (1938) failed to produce remissions by artificial hyperbilirubinaemia suggests that the jaundice owes its effect to something more than the mere accumulation of bile in the blood stream.

The changes in the E.S.R. which occur in infective hepatitis have already attracted considerable attention. The view has been expressed that the inhibitory effect which is present while the patient is jaundiced may be due to an increase of bile salts in the blood (Miles, 1945). Recent work, however, has shown that the blood level of free and conjugated cholic acid in infective hepatitis is very little raised. In the 22 cases studied by Sherlock and Walshe (personal communication) it never approached the levels required to produce the retardation obtained in the *in vitro* experiments of Miles. The E.S.R. is known to be affected by minute changes in the protein composition of the fluid in which the red cells are suspended (Gordon and Wardley, 1943), and a temporary rearrangement of the blood proteins undoubtedly occurs in the early weeks of infective hepatitis (Gray and Barron, 1943). Whether such a change is capable of exerting a favourable effect on arthritic conditions is still unknown, but further investigations might reveal some relation between these changes and the temporary improvement in the joints.

The remissions which are induced in rheumatoid arthritis by an attack of jaundice are striking, and show that the disease is capable of undergoing considerable regression. They are unfortunately temporary, and treatment of rheumatoid arthritis by jaundice cannot be recommended for general use. Though the immediate improvement is more dramatic the long-term results are inferior to those of gold. Only in the field of research is the induction of jaundice in patients with rheumatoid arthritis justifiable. Here it provides an opportunity of producing a remission under controlled conditions and the possibility of analysing the mechanism by which it is produced.

Summary

Jaundice was induced in 32 patients with rheumatoid arthritis, and temporary improvement in the latter condition was obtained in 25 cases.

The remissions were unequal in degree and of short duration. Ten patients became completely free from pain and swelling, and 15 showed some improvement. The average period during which optimal improvement was observed was 42 days, but a longer time elapsed before the joints reverted to their pre-icteric condition.

Complete freedom from pain and swelling was obtained more often in patients who had had rheumatoid arthritis for less than 5 years than in those who had had it for more than 5 years.

There was no definite relationship between the intensity of the jaundice and the type of remission evoked.

In many cases a fall in the E.S.R. was noticed during the icteric phase. This was followed by a rise to a level above that recorded before jaundice was induced. These changes did not necessarily correspond to changes in the joint condition. A similar phenomenon has been observed when patients with active tuberculosis develop infective hepatitis.

The suggestion is put forward that improvement in the joint condition and the changes in the E.S.R. may be related to changes in the plasma proteins, but no evidence is available to support this view.

The induction of jaundice in rheumatoid arthritis is justifiable only as a research measure. Its aim is to identify the substance or mechanism responsible for the remission of the joint condition and ultimately to reproduce this mechanism by other less dangerous methods.

This therapeutic trial was carried out with the support of the Jaundice Committee of the Medical Research Council. Many of the investigations were made at centres other than Oxford, and we are indebted to the staff and management of the Royal Sheffield Infirmary and Hospital, the City General Hospital, Sheffield, the Montagu Hospital, Mexborough, and the Liverpool Royal Infirmary, for providing unique facilities and help. It would have been impossible to carry out the work unaided, and we wish particularly to acknowledge the friendly co-operation and help of Prof. Barnes and Prof. Wayne, Dr. Abercrombie, Dr. Imrie, Dr. Barrie, and Dr. Brodie, of the Royal Sheffield Infirmary and Hospital; Dr. Clark and Dr. Milne, of the City General Hospital, Sheffield; and Prof. Henry Cohen and Dr. Simonds of the Royal Infirmary, Liverpool.

ACUTE NON-SPECIFIC MESENTERIC LYMPHADENITIS

BY

IAN AIRD, Ch.M., F.R.C.S.Ed.

(From the Department of Surgery, University of Edinburgh, and the Royal Edinburgh Hospital for Sick Children)

Although often described in British, American, and other medical literature, acute non-specific mesenteric lymphadenitis has found no general acceptance as one of the commonest causes of acute abdominal pain in children and as an occasional puzzling affection of adults. As a rule the term is omitted from the index and text not only of surgical manuals but even of encyclopaedic reference works, and there are hospitals in which all inflammatory enlargements of abdominal lymphatic glands are presumed to be tuberculous. If the condition is mistaken for acute appendicitis, as it frequently is, no great harm is done; it may be wise to sacrifice accuracy for safety. Material injustice may be caused, however, if the disease is wrongly labelled tuberculosis: the patient's medical record is distorted, relatives are subjected to unnecessary anxiety, and later the premium for a life insurance policy may be loaded. Acute non-specific mesenteric adenitis is commoner in this country now than is acute abdominal tuberculosis; during last year the incidence of the disease has increased, and in my charge in the children's hospital there have been admitted during the year 37 patients suffering from non-specific adenitis, as compared with 83 suffering from acute appendicitis and four suffering from abdominal tuberculosis. These figures are only very roughly approximate; they underestimate the incidence of non-specific adenitis in children: a considerable number of children in whom a diagnosis of non-specific adenitis has been made in the out-patient department have not been admitted, but have confidently been allowed to go home.

Pathological Features

To the previous description of Wilensky (1920), Foster (1938), Klein (1938), and others there is little to add. The mesenteric glands—*juxta-intestinal* along the mesenteric attachment of the lowest few feet of ileum, *intermediate* along the ileal arteries, and *terminal* on the main superior mesenteric trunk—are discretely enlarged. The first or the last of these groups may be involved alone, or all three groups may suffer together. The anterior and posterior caecal and the ileo-colic glands may or may not be simultaneously affected. The juxta-intestinal glands are predominantly involved in early stages of the disease; early in an attack they may be pink in colour, but usually they are found to be white. The intermediate and terminal glands are predominantly affected in later stages of the disease; they seem always to be white in colour. The enlarged glands are soft and juicy at first, elastic later, and finally quite hard; it is uncertain whether calcification ever occurs in non-tuberculous adenitis. Suppuration has been recorded in the mesenteric glands, but usually as a result of specific bacterial infection.

The leaves of the mesentery, and, if the terminal superior mesenteric glands are involved, the adjacent peritoneum of the posterior abdominal wall, may be congested. The peritoneum of the anterior abdominal wall is nearly always unaltered; I have found it slightly inflamed only once, in an adult. The ileum, and sometimes the caecum and appendix as well, may show serous hyperaemia, and sometimes a palpable oedema of the whole thickness of the bowel wall. This inflammatory appearance of the intestine is commonly found only during earlier attacks of the disease. Seldom of more than slight degree, it may be absent even in a first attack; it may affect a considerable length of lower ileum, or several discrete stretches of bowel, or only one short segment; or it may be restricted merely to palpable thickening of Peyer's patches. Frequently, with or without an inflammatory appearance of the bowel, there is a small quantity of clear fluid free within the peritoneal cavity.

Histologically the glands present a non-specific hyperaemia and cellular hyperplasia. In my experience, glands removed at operation, and free fluid from the peritoneal cavity, prove sterile on culture and on animal inoculation.

Symptoms

The history is not particularly characteristic. The patients, more often male than female, are usually children beyond the years of infancy, but the condition has been recorded at 10 months and at 70 years of age; the extremes in my own series have been 3 and 39 years. The pain is essentially a general abdominal colic, often of extreme severity, and more intense and alarming than the initial colic of appendicitis in childhood. Between spasms of colic there is entire freedom from pain, and the patient is happier and livelier between spasms than is any patient who harbours an inflamed appendix. Even during the actual attack of pain the patient moves freely always, and violently sometimes, with a constant changing of position which would be unusual in acute appendicitis. As in appendicitis, when the patient who has given a history of generalized abdominal pain is asked to indicate the site of most intense pain, he points to the right lower quadrant. In contrast to the patient with acute obstructive appendicitis, however, he cannot locate the site of maximum pain precisely, but indicates an ill-defined area on the right side. When first seen by a doctor, four out of five patients tell of a previous attack, and most have had more than one previous attack of an almost precisely similar character. Nausea, usually with vomiting, accompanies one at least of the initial attacks. Diarrhoea is exceptional. There has quite often been a recent sore throat or other upper respiratory infection.

Signs

Clinical examination provides no more specific evidence than does the history. The patient may seem little affected, except by pain, or may be flushed and obviously fevered, or pale; he is seldom or never prostrated or ominously motionless, and during the examination limb and body movements occur normally. If taken early in an attack, the temperature is elevated to 101° or even substantially higher, and on the first day also there is an almost invariable leucocytosis of 15,000 to 20,000, with 80% or more of granular cells. As a rule the white count falls again on the second day—its elevation is quicker, higher, and shorter-lived than in acute appendicitis. A bright-red pharyngitis is a not unusual concomitant of non-specific mesenteric adenitis, but neither its presence nor its absence is highly significant, for in more than 70% of my cases pharyngitis has not been detected, and acute pharyngitis sometimes closely precedes acute appendicitis.

On abdominal examination, tenderness is elicited in the right iliac fossa, higher and more medial than the usual tenderness of acute appendicitis. The lowest limit of tenderness is just below and to the right of the umbilicus. When the terminal (superior mesenteric) glands are widely involved a band of tenderness may be outlined as it extends upwards and to the left towards and sometimes just beyond the midline of the epigastrium. The right lower abdominal muscles are nearly always in slightly higher tone than their fellows of the opposite side, but rigidity is not maximal or, if it is, the muscles soften perceptibly under continued gentle pressure. Rebound tenderness is not unusual, particularly if the leaves of the mesentery are inflamed, or the serosa of the bowel. I have never elicited pain in the right iliac fossa by palpation of the left. One sign, "shifting tenderness," is said to be pathognomonic; certainly its presence is most suggestive, though its absence is not significant. To elicit shifting tenderness the site of maximum tenderness is located while the patient lies supine; the position is then changed to the left lateral, and after a few minutes, if the sign is present, the point of maximum tenderness will be found to have moved leftward to or beyond the midline. The sign depends upon postural displacement of the lower ileum with its mesentery, and is elicited only if the juxta-epiphysial glands are inflamed. Rarely it may be positive early in acute appendicitis if the caecum is highly mobile.

The enlarged glands are seldom palpable, even those at the root of the mesentery fixed against the background of the posterior abdominal wall, and free fluid is not often of sufficient amount to be detected by percussion.

It would be easy to elaborate degrees and varieties of acute mesenteric lymphadenitis, based on the severity of the symptoms and on the gland groups affected, but any too detailed classification is artificial, for degrees and varieties merge imperceptibly into each other, and a single patient may manifest at different times all degrees of severity, all combinations of symptoms and signs, and, in cases submitted to more than one operation, more than one variety of pathological picture. A chronic form of the disease has been described, but seldom has any kind of continued and prolonged ill-health been proved to be due to non-specific adenitis. In this disease attacks are commonly recurrent, but they are separated by periods of a few months' freedom from discomfort: persistent ill-health and frequently recurring fever and pain, with constant abdominal discomfort, have been found to be due nearly always to tuberculous rather than to non-specific adenitis if laparotomy has finally offered an opportunity for biopsy.

Differential Diagnosis

Safety demands that acute appendicitis be distinguished from lymphadenitis; justice and accuracy demand that non-specific be distinguished from tuberculous adenitis. Other causes of abdominal pain, numerous though they are, offer less difficulty in differentiation.

Confusion with appendicitis is less likely to occur in practice than seems possible when the symptoms and signs of the two conditions are compared on paper. The sharp spasms of colic with complete or almost complete freedom from pain between them, the rolling and kicking of the child in an attack, the high and medial situation of the tenderness, the absence (if it is absent) of rebound tenderness even at the point of maximum tenderness, the presence (if it is present) of shifting tenderness, the relaxation under steady pressure of apparently rigid muscles, and the history of previous typical recurrent attacks, if these have occurred, all inspire confidence in a negative diagnosis of "this is not appendicitis" even if they fail to suggest the positive diagnosis of non-specific mesenteric adenitis. If such a pathological condition did not exist it would almost be necessary to invent it as an answer to the question, "If it is not appendicitis, then what is it?" If the term "non-specific mesenteric adenitis" is adopted for official record purposes, in any charge, five important sequels are observed, and cannot be entirely ascribed to misguided and indiscriminate enthusiasm:

(1) The syndrome of non-specific mesenteric adenitis is found to lose the vagueness of its verbal description.

(2) A considerable number of patients are found suitable for inclusion in the adenitis group.

(3) Acute appendicitis can be excluded with greater certainty and with less anxiety.

(4) Substantially fewer normal appendices are removed.

(5) The incidence of "mural appendicitis" and "non-obstructive appendicitis" falls.

That there is no danger in attempting to distinguish appendicitis from lymphadenitis has been shown in my own charge; during the past two years only three children suffering from non-specific mesenteric adenitis have been mistakenly subjected to appendicectomy, yet the converse error—delay in removing a diseased appendix due to a misdiagnosis of mesenteric adenitis—has not occurred.

Differentiation of non-specific from tuberculous mesenteric adenitis is not always easy. In the latter condition leucocytosis is usually absent throughout, the abdominal wall is almost completely lax, enlarged matted glands are usually palpable, and pain or at least discomfort is more constant between attacks. If operation is not performed, and doubt exists, it is not only more accurate, but it serves better the interest of patient and of community, to regard the condition as non-specific unless there is clear evidence of tuberculosis elsewhere —in neck or chest, for example. If the question arises at operation, a diagnosis of tuberculosis is justifiable only if surface tubercles are seen, or if the glands are matted and partly caseous, or if the tuberculous nature of the condition is proved by biopsy.

Other forms of mesenteric gland enlargement seldom produce acute abdominal symptoms. At operation, malignant glands can usually be recognized by their character. In lymphadenoma and infectious mononucleosis glands elsewhere in the body are simultaneously enlarged. Even so, it is wise in non-specific adenitis to carry out a differential white count and the Paul-Bunnell test.

Pathogenesis

It might be argued that the causes of mesenteric gland enlargement are so numerous that this condition cannot be regarded as a pathological entity, yet the clinical features are so commonly repeated in characteristic combination, and are associated with such uniform pathological appearances, that in the light of our present knowledge it would seem expedient to regard the disease as clinically and pathologically distinct, even if it should be proved in the future to be due to more than one cause.

The appearances in the glands, and more especially the appearances, when they are present, in the wall of the intestine, are those of acute inflammation, and strongly suggest a response to infection (Stephens, 1938). It would be unjustifiable, however, to class the condition as an enteritis, for at operation the glandular enlargement is invariable, whereas the appearances of inflammation in the bowel, at least from its serious aspect, are exceptional. Foster (1938) and Adams and Olney (1938) have suggested that the appendix is the portal of entry to the inflamed glands and, admittedly in a few cases but by no means in all, the appendix shows the same serous flush as may the neighbouring ileum. The appendicular origin of non-specific adenitis, however, is difficult to substantiate when it is remembered that the juxta-ileal glands, predominantly and invariably enlarged in the early case of adenitis, are not found enlarged at operations for overt appendicular infections (Wilensky and Hahn, 1926) unless perforation and peritonitis have supervened: the appendicular lymphatics drain to the ileo-colic glands, and thence direct to the terminal superior mesenteric group. Felsen (1935) suggested that organisms of the dysenteric group might be responsible, but these organisms can rarely be cultured from the stool, and Klein (1938) found a positive agglutination reaction in only three patients out of 30 tested. Tuberculosis can confidently be excluded in most of those cases which show no tubercle formation to the naked eye, no matting, and no caseation, and in which tubercle bacilli cannot be isolated from lymph glands or peritoneal fluid, guinea-pig injection is negative, and the histological picture is not that of tuberculosis. Rosenburg (1937) found a smaller percentage of positive tuberculin reaction in patients suffering from non-specific mesenteric adenitis than in controls suffering from other acute non-tuberculous abdominal conditions. Non-specific adenitis has been ascribed to the passage of a hypothetical virus through the mucosa of the intestine to its submucous lymphatic tissue, and thence to the mesenteric glands. Some support is lent to this hypothesis by the failure to culture bacteria from glands which are apparently the seat of acute inflammation. The coincidence or precedence of upper respiratory tract infection is an additional argument in favour of a more or less generalized virus infection, though most observers find respiratory infection much less common in mesenteric adenitis than do Adams and Olney (1938), who regard mesenteric adenitis as "a local manifestation of a generalized condition from upper respiratory tract infection."

A relationship might be suggested between mesenteric lymphadenitis and the acute regional ileitis of Crohn. The gland enlargement in the mesentery of the affected bowel in regional ileitis is identical with that seen in non-specific mesenteric adenitis; indeed, it *is* a non-specific mesenteric adenitis. Conversely, an early non-specific adenitis accompanied by a patchy pink inflammation of the serous coat of ileum and, more significantly still, by an oedema of all coats sharply demarcated from healthy bowel, suggests an early, mild, self-limiting regional ileitis; indeed, it *is* a regional ileitis in the widest sense of the term. The identity or diversity of the two conditions could be proved only by the demonstration of the ultimate cause of one of them or the causes of both.

Treatment

Little can be said of treatment. Appendicectomy is specifically advised by some. Foster (1939) claims that if appendicectomy is performed patients seldom report a return of pain after operation, but that those treated conservatively usually complain of recurrence. His argument is not conclusive, however, for abdominal pain is always regarded more anxiously by a child's parents if the appendix is present than if the appendix has been removed. Abdominal pain of any kind except the most severe, occurring after appendicectomy, seldom brings a child to his doctor. Rosenburg (1937), in a careful follow-up, finds that two-thirds of the patients treated by appendicectomy for non-specific adenitis do in fact have a recurrence of pain after operation. My own experience is similar to that of Rosenburg and of Adams and Olney in that it gives no reason to believe that appendicectomy affects the course of the disease, which in any case is self-limiting and from which ultimate recovery seems to be invariable.

Summary

The desirability is argued of recognizing acute non-specific mesenteric lymphadenitis as a clinical and pathological entity.

The frequency of this condition is compared with that of acute appendicitis and of tuberculous mesenteric adenitis.

The pathological features and the distribution of affected glands are described.

The possibility of a pre-operative diagnosis is discussed, and the diagnostic value of such signs as localized tenderness, rebound tenderness, and shifting tenderness is assessed.

The evidence supporting various hypotheses of pathogenesis is weighed, and virus infection is accepted as the most probable cause of the condition, in spite of a present lack of full bacteriological proof.

The Ministry of Health has sent to port health and riparian authorities in England and Wales a circular letter enclosing the new Port Health Amendment Regulations, 1945, which have been made by the Minister under the Public Health Act, 1936, and will come into operation on Dec. 1. Their purpose is primarily to give effect to the provisions of the International Sanitary Convention, 1944, so far as those provisions affect the Port Sanitary Regulations, 1933. This convention, modifying the International Sanitary Conventions of 1926 and 1938, has recently come into force following its signature by the necessary number of Governments. It is now on sale as a Command Paper (Cmd. 6637). The opportunity has been taken to introduce some amendments of the 1933 Regulations which experience has shown to be desirable and which can, without inconvenience, be made at the present time. The form of declaration of health has been revised, and it will be the duty of port health and riparian authorities to furnish copies of it to the master of every foreign-going vessel arriving in England and Wales from a foreign port. Other changes in general procedure are intended to clarify existing instructions and to tighten control. The new Port Health Amendment Regulations are published by H.M. Stationery Office at 2d. as Statutory Rules and Orders, 1945, No. 1282.

THE DIETS OF SCHOOL-CHILDREN IN TWO INDUSTRIAL TOWNS

BY

E. R. BRANSBY, M.Sc., Ph.D.
(Ministry of Health)

AND

GERTRUDE WAGNER, M.A.
(Wartime Social Survey)

The vitamin-feeding tests made in Ipswich and Glossop in 1941–2 (Bransby *et al.*, 1944) included no dietary data to show the vitamin intakes obtained from the diets. The studies to which this report relates were designed to provide dietary information for a sample of the children participating in similar feeding tests in two North of England industrial towns, A and B.

Method

Two dietary surveys were made in both A and B, the first in Aug./Sept., 1943, and the second in March, 1944. These two periods were chosen because during the former vegetables were relatively plentiful and during the latter relatively scarce. Over 5,000 children participated in the feeding tests; a random sample of children was selected from the school lists for inclusion in the dietary survey. Dietary data were collected in March, 1944, only for those children for whom such data had been obtained in Aug./Sept., 1943. Data were obtained for 426 children in Aug./Sept., 1943, and 289 in March, 1944.

Shortly before the survey began the mothers of the children selected for study were sent a letter signed by the medical officer of health, asking for their co-operation by recording during one week the amount of food eaten by their children. During the week the dietary data were recorded each of the co-operating mothers was visited at least three times by a field worker of the Wartime Social Survey, who checked the dietary data and collected other relevant information.

The method used for collecting the dietary data was evolved after trials which had shown that it was acceptable to and workable by the large majority of a randomly chosen sample of working-class housewives. That it proved so is shown by the fact that in the Aug./Sept. survey only 22% of the mothers refused to co-operate —some of these for unavoidable reasons. All foods, where possible, were recorded in "homely measures." Milk was measured in cupfuls, and the size of the cup was also measured; bread was recorded in slices, and the number of slices cut from a loaf was counted or a sample of slices was weighed; standard tablespoons were provided for serving such foods as vegetables, breakfast cereals, and puddings; standard teaspoons were provided for serving sugar and jams. Each mother was also given a poster with illustrations of variously sized pieces of meat, cheese, jam tart, and steamed pudding, and different-sized potatoes. In addition, the poster included a diagram showing the amount of potato to be served in each tablespoonful. The amount of food eaten by each child during the week was calculated from the number and the weight of units of the various foods eaten. Trials have shown that the average intakes of nutrients by groups of children found by this method tended to be just slightly greater than those obtained by the precise technique of Widdowson and McCance (Widdowson, 1936; Widdowson and McCance, 1936).

School Meals.—Special steps were taken to ascertain the amount of food provided in the school meals in A and B. For two or three weeks immediately before or during each survey period representative meals served to children of different ages and attending different schools were weighed to determine the amounts of the various foods provided. Information was then obtained on the school meals actually provided during the survey period. The total food intake of children eating school meals was the sum of the food provided at home and that provided at school. For all children, information was obtained for the amount of "school milk" consumed.

Ascorbic Acid Content of the Diets.—Special attention was given to the ascorbic acid content of the diet, because the amount of ascorbic acid in vegetables is very variable and because multivitamin capsules provided a supplement of 25 mg. a day. It was hoped that information on the amount of vegetables eaten and the methods of cooking them would enable reasonably accurate estimates to be made of the actual ascorbic acid intakes of the individual children. The mothers were therefore asked for details of the methods by which the vegetables were cooked and the ascorbic acid content was estimated from the information provided. The following percentage retentions of ascorbic acid in green vegetables were allowed:

Cooked in little water	60% retention
About half covered with water	40% ,,
Completely covered with water	20% ,,
Length of time kept hot	50% per hour loss

For potatoes and root vegetables the factor of 50% retention was adopted throughout. In addition, samples of cooked vegetables collected from homes and schools were analysed for ascorbic acid by Dr. Neil Jenkins. The values found for the different schools were applied directly for estimating the ascorbic acid intakes of children eating school dinners. The results of the study of the ascorbic acid values of home-cooked vegetables will be published separately by Dr. Jenkins. He found that there was good agreement between the average values of a number of samples determined by analysis and by calculation as described above, but that there was little agreement between the two values for individual samples of cooked vegetables.

Standards of Nutrient Requirements.—The League of Nations (1938) standards of nutrient requirements were used for comparing the average nutrient intakes both of groups of children and of individual children with their estimated needs. The age groupings used by Magee (1943), whose standards of requirements were based on those of the League of Nations, were too wide for the present purpose, and standards for yearly age groups were obtained from them by interpolation. An estimate was also made of the adequacy of the nutrient intakes of the individual children by comparing their actual intakes with the estimated requirements of children of the same age. The intake of each nutrient was graded "adequate" if it reached the level of the League of Nations standards, "fair" if it was within two-thirds of that standard, and "poor" if below two-thirds. It is appreciated that this method of classification has severe limitations because of the wide variation in individual requirements, as has been amply demonstrated by Wiehl (1944).

Standards of "Cost Coefficients."—For the purpose of demonstrating the dietary intakes at different levels of food expenditure the children were grouped according to the "food expenditure per expenditure unit" of the families to which they belonged. The procedure was as follows. The cost of adequate diets was estimated for persons of different ages; the cost of the diet of an adult male was reckoned as one expenditure unit and the cost coefficient of all other persons was calculated from the relative cost of their diets and that of the adult male. The "food expenditure per expenditure unit" for each family was obtained by dividing the actual food expenditure per week by the number of food expenditure units in the family. The standards used are given below.

TABLE I.—*Cost Coefficients (Cost of an adequate diet for an adult male was calculated to be 9s. 6d. per week at the time of the surveys)*

	Full Price*	Free School or National Milk	Free Dinners†
Adult male	1·00	—	—
„ female	0·93	—	—
Expectant and nursing mothers	1·25	1·10	—
17–21 years	1·00	—	—
15–17 „	1·05	1·03	0·76
12–15 „	1·03	1·01	0·75
7–12 „	0·82	0·80	0·61
5–7 „	0·63	0·61	0·38
3–5 „	0·52	0·39	—
1–3 „	0·40	0·28	—

* Includes school and national milk and vitamin concentrates at reduced price
† Allowance for school dinners: one-third daily cost of food, five days per week.

Table of Food Composition.—The values submitted to the Sub-committee on Food Composition of the Accessory Food Factors Committee of the Medical Research Council supplemented by values given in *The Chemical Composition of Foods* (McCance and Widdowson, 1940) were used for calculating the nutrient values of the diets.

Presentation of Results.—A large number of tables were prepared from the analysis of the data collected during the two surveys. Generally four sets of tables were obtained for each classification: (1) the actual intake of foods or made-up dishes per head per week; (2) the actual nutrient intakes per head per week; (3) the percentage of estimated requirements represented by the latter; and (4) the percentage of the children whose nutrient intakes were adequate, fair, or poor. The principle adopted for selecting the tables for inclusion in this report was to give priority to (3).

Results

Average Intake of Food and Nutrients.—Table II shows the percentage of nutrient requirements consumed by boys and girls in A and B as found in the Aug./Sept., 1943, and March, 1944, surveys. The average calorie and protein intakes were adequate in both surveys. The calcium intakes were deficient by about 40%, and the iron intakes in March, 1944, tended to be somewhat below requirements. Slightly less than half the vitamin A potency was provided by carotene, the remainder being preformed vitamin A from either the diet or the cod-liver oil. The ascorbic acid intakes were 118–150% of requirements in both surveys, but the intake during March, 1944, was raised above the normal level for that season of the year by a distribution of oranges during the survey period. Without the ascorbic acid provided by the oranges the average intake in March, 1944, would have been of the order of 20–25 mg. a day. The difference between this intake and that in Aug./Sept., 1943, was due to a lower consumption of green vegetables and the lower ascorbic acid value of potatoes. The proportion of children who had diets poor in the various nutrients are as follows, the first figure relates to Aug./Sept., 1943, the second to March, 1944: calories, 13% and 20%; protein, 3% and 6%; calcium, 64% and 67%; iron, 8% and 14%; vitamin A, 17% and 33%; vitamin B, practically none; ascorbic acid, 4% and 20%. It is probable that a much higher proportion of children would have had a poor intake of ascorbic acid in March, 1944, but for the distribution of oranges.

TABLE II.—*Percentage of Requirements Consumed by Boys and Girls in A and B*

	No. of Children	Calories	Protein	Calcium	Iron	Vit. A	Vit. B_1	Vit. C
				Aug./Sept., 1943				
Town A: Boys and girls	172	108	111	63	109	130	136	150
Town B: Boys and girls	254	107	116	61	105	115	140	133
				March, 1944				
Town A: Boys and girls	116	103	110	61	98	101	140	118
Town B: Boys and girls	173	97	107	57	88	199	133	118

Table III shows the consumption of certain foods, per head per week, in Aug./Sept., 1943, and March, 1944. It must be noted that the weights, etc., refer to foods as eaten—that is, cooked edible portion—and not foods "as purchased."

TABLE III.—*Average Weekly Consumption of Certain Foods*

	Aug./Sept., 1943	March, 1944
Meat, bacon, and fish	15 oz.	17 oz.
Stews, soups, pies, etc.	22 oz.	28 oz.
Eggs	1	1
Cheese	2 oz.	3 oz.
Bread, etc. (as flour)	55 oz.	60 oz.
Potatoes	41 oz.	44 oz.
Porridge and other breakfast foods	14 oz.	14 oz.
Vegetables, green	7 oz.	5 oz.
„ others	12 oz.	15 oz.
Fruit and tomatoes	41 oz.	5 oz.
Fats	7 oz.	6 oz.
Sugar and preserves	11 oz.	10 oz.

The consumption of all forms of milk, including an estimated amount used in puddings, was of the order of the equivalent of 5 pints per head per week. The principal difference between the consumption of the various foods in Aug./Sept., 1943, and March, 1944, was the greater consumption of stews, etc., and bread at the latter time, and milk and fruit and tomatoes at the former. The higher consumption of fruit and tomatoes in Aug./Sept., 1943, was due to a glut of tomatoes at the time of the survey.

Nutrient Intakes on Various Days of the Week.—The data collected in the Aug./Sept., 1943, survey were analysed to show the nutrient intakes for the sample as a whole—that is, 426 children—on each day of the week. In Table IV daily intakes are expressed as percentages of the average daily intake for the whole week.

TABLE IV.—*Comparative Intake of Nutrients by Day of Week*

	Calories	Protein		Fat	Carbohydr.	Calcium	Iron	Vit. A	Vit. B_1	Vit. C
		Anim.	Veg.							
Sun.	102	106	100	104	100	89	108	121	111	133
Mon.	101	94	100	99	103	102	92	89	102	95
Tues.	99	97	100	100	99	105	100	101	96	86
Wed.	101	106	100	101	99	108	100	114	95	93
Thurs.	96	97	100	97	101	106	100	98	98	98
Fri.	101	106	100	102	100	109	100	85	98	95
Sat.	96	86	98	96	97	82	100	93	98	98

The differences in nutrient intakes on the different days of the week were not pronounced. The diet was slightly more generous on Sundays and that on Saturday slightly less generous than on other days of the week. On both of these days the calcium intake was less than on other days, owing presumably to the absence of school milk.

Nutrient Intake According to Age.—The data of each survey were analysed to show the average daily nutrient intake for yearly age groups. Table V shows the average intakes for boys and girls and for both surveys combined.

Table V.—*Daily Nutrient Intakes According to Age*

Age (yrs.)	No. of Children	Protein		Fat	Car-bo-hydr.	Cal-ories	Cal-cium	Iron	Vit. A	Vit. B_1	Vit. C
		Anim.	Veg.								
		g.	g.	g.	g.		g.	mg.	i.u.	i.u.	mg.
5	23	30	36	82	279	2,100	0·84	10	3,400	380	35
6	71	36	37	93	281	2,250	0·92	11	3,700	420	35
7	70	31	37	82	272	2,100	0·80	10	2,800	410	33
8	91	36	37	88	277	2,200	0·89	11	3,700	430	38
9	113	35	40	89	293	2,250	0·84	12	3,300	450	39
10	79	33	43	82	300	2,250	0·80	12	3,500	450	38
11	69	36	48	93	332	2,500	0·86	14	3,500	500	43
12	124	37	50	95	348	2,600	0·84	14	3,400	530	44
13	71	37	55	100	363	2,700	0·89	15	3,400	550	42

Compared with the League of Nations standards of requirements the mean calorie intakes were sufficient below about 7 years and slightly insufficient at 12–13 years; protein intakes slightly insufficient at 12–13 years; calcium intakes about 40% deficient at all ages; iron intakes somewhat insufficient above 10 years; and the vitamin intakes sufficient at all ages. The differences between the actual calorie intakes and calorie requirements were fairly substantial, the former being in excess of the latter by about 500 calories for children of below 7 years and 300 calories below for children of 12–13 years. It is apposite in this connexion to state that Cook, Davidson, Keay, and McIntosh (1944) found that the average intake of 45 boys aged 14–15 years was 2,228 calories daily, which is about 700 calories daily lower than the League of Nations standards, and that Virtue and McHenry (1945) found that the mean calorie intake of every type of person was below the recommended allowances (National Research Council of the U.S., 1943), and in some cases markedly so.

Nutrient Intake According to Food Expenditure per Expenditure Unit.—Data on food expenditure could not be obtained from all the mothers co-operating in the survey; hence the sample entering this analysis is smaller than that for other analyses. Table VI shows the percentage of nutrient requirements consumed according to food expenditure per expenditure unit.

Table VI.—*Percentage of Nutrient Requirements Consumed According to Food Expenditure per Expenditure Unit*

In general there was for all nutrients an increase in adequacy of intake with increasing expenditure per expenditure unit. The calcium intake was low at all expenditure levels, but, apart from that, diets were on the average adequate at expenditures of about 11s. per expenditure unit per week. The improvement in the diet with increasing food expenditure per expenditure unit was due to small increases in the consumption of meat, fish, milk, puddings, cake, cereal breakfast foods, potatoes, green vegetables, and fruit. The consumption of bread tended to decrease with increasing expenditure.

Table VII shows the percentage of children with adequate nutrient intakes, in each survey, according to food expenditure per expenditure unit.

* For calcium these represent the percentage of children with *poor* intakes.

The percentage of children with adequate intakes decreased as food expenditure per expenditure unit decreased. In the under 11s. group a large proportion of the children had a diet deficient in some respect. Even in the higher expenditure groups, for which the actual expenditure on food was more than sufficient to purchase an adequate diet, many children had diets insufficient in some nutrients. This indicates that the inadequate intakes were to some extent due to unwise spending of the money available.

Nutrient Intake According to Size of Family.—There was, on the average, little change in adequacy of the diets with changes in family, except that the larger the family the smaller the intakes of vitamin A and ascorbic acid. An increase in family size was accompanied by an increased consumption by the child of bread and porridge, and a reduced consumption of meat, fish, puddings, cake, breakfast cereals, and fruit.

Table VIII shows the percentage of children receiving adequate diets according to family size.

* For calcium the percentage refers to children with *poor* intakes.

A somewhat higher proportion of children belonging to large families compared with those belonging to small families had inadequate nutrient intakes. There was, however, a reverse tendency for calcium.

Diets of Children taking and not taking School Dinners.—The data from each survey were analysed to compare for towns A and B the adequacy of the total diet of children taking and those not taking school dinners. The results are given in Table IX.

Table IX.—*Adequacy of Nutrient Intakes according to whether School Meals taken or not taken. Percentage of Requirements Consumed*

No school meals	107	94	106	54	85	93	130	128

In A the diet of children taking school dinners was not, on the average, quite as good as that of those not taking school dinners, while the reverse was true for B. Special studies showed that the school dinners provided in B were somewhat better than those provided in A. Children eating school dinners had a somewhat higher average consumption of meat, puddings, and potatoes than did children not eating school dinners.

Diets of Children According to whether Mother was or was not Working Outside the Home.—Table X shows the percentage of

requirements consumed by children according to whether the mother was working full time, part time, or not at all, outside the home. The data from both surveys show that the diets of children whose mothers did not go out to work were generally somewhat better than those whose mothers went to work, either full or part time.

Discussion

The purpose of the surveys described in this report was to obtain a picture of the food consumption of a sample of the subjects of the vitamin-feeding tests in towns A and B. For this the data were analysed principally in two ways: by considering the adequacy of the nutrient intakes of the whole sample, or subgroups of children within the sample, and by grading the nutrient intake of individual children into one of the categories "adequate," "fair," or "poor." It is with some hesitancy that the latter results have been included in this report, as they are rightly open to criticism. For this grading it was necessary to compare the individual child's intake of each nutrient with uniform standards of nutrient requirements. Wiehl (1944) found no agreement between estimated calorie expenditures and calorie intakes, and there is little doubt that for all nutrients there are considerable differences in individual requirements which invalidate the adoption of a single standard for all children. Also, the variations in the composition of foods and made-up dishes may result in considerable errors in the estimation from food tables of the nutrient intakes of individuals. Further, small differences in standards of nutrient requirements may make an appreciable difference in the number of children falling into the various categories (U.S. Dept. of Agriculture, 1941). Hence the figures given for the proportion of children falling into the various categories can only be broadly interpreted, being intended merely to make the order of the deficiencies of the nutrient intakes.

The diets of the children studied were, on the average, generally adequate in all nutrients except calcium, for which there was a deficiency according to the adopted standard, 1.4 mg. a day, of about 40%. The large majority of the children had poor intakes according to that standard. Although the average intakes of the other nutrients were fairly adequate, a considerable proportion of children had poor intakes of calories, iron, vitamin A, and vitamin C, while many had only fair intakes. Reference has already been made to the ascorbic acid intake during March, 1944, and this was raised above the normal level for that month by a chance distribution of oranges. There is little doubt that it was customary at that season for some children to receive but a few milligrammes of ascorbic acid daily from their diet. One such group of children were those regularly taking school dinners cooked a considerable time before being eaten, with the result that a large part of the ascorbic acid present in the vegetables was destroyed. Actual determinations showed that the school dinners served in B in March, 1944, provided 2 to 19 mg. of ascorbic acid a day. Children eating school dinners receive the major part of their ascorbic acid from that source, and it is apparent that the ascorbic acid intake of those taking the dinners provided at certain schools must have been very small.

The adequacy of the diet did not change as much as was expected with an increase in the size of the family to which the child belonged, although there was undoubtedly some worsening. No similar pre-war data are available for comparison, but family surveys showed that the adequacy of the family diet worsened as family size increased (County Council of the West Riding of Yorkshire, 1939). In the present study the gradient was fairly steep for the relationship between adequacy of nutrient intake and food expenditure per expenditure unit. Thus in the Aug./Sept., 1943, survey the adequacy of the calorie intake improved from 94% to 128%, and the protein intake from 101% to 133%, with an increase in the food expenditure per expenditure unit of from under 9s. to over 19s. per head per week.

Summary

Data on the food consumption of 426 school-children in Aug./Sept., 1943, and 289 in March, 1944, were collected in two towns, A and B. As part of this investigation studies were made of the nutritive value of the school meals provided and the ascorbic acid content of home-cooked vegetables and of vegetables provided in school meals.

In both Aug./Sept., 1943, and March, 1944, the diets in A and B were on the average satisfactory, except for the calcium intakes, which were about 40% deficient according to the League of Nations standards. The proportions of children who had diets poor in the various nutrients are as follows, the first figures relating to Aug./Sept., 1943, the second to March, 1944: calories, 13% and 20%; protein, 3% and 6%; calcium, 64% and 67%; iron, 8% and 14%; vitamin A, 17% and 33%; vitamin B, practically none; ascorbic acid, 4% and 20%.

The data collected in Aug./Sept., 1943, were analysed to show the nutrient intakes on the various days of the week. The differences between the various days were small, the diet being slightly more generous on Sunday and slightly less generous on Saturday.

The nutrient intakes by children of various ages were compared with the League of Nations standards of nutrient requirements. The mean calorie intakes were sufficient below about 7 years and slightly insufficient at 12–13 years; protein intakes were slightly insufficient at 12–13 years; calcium intakes about 40% deficient at all ages; iron intakes somewhat insufficient above 10 years; and the vitamin intakes sufficient at all ages.

Generally the adequacy of the intake of all nutrients improved with increasing "food expenditure per expenditure unit." Also the proportion of children with poor nutrient intakes decreased as food expenditure per expenditure unit increased.

There was a tendency for a greater proportion of the children belonging to large families to have unsatisfactory nutrient intakes than for children belonging to small families.

In the town where the school dinners were satisfactory the diets of children taking school dinners were better than those of children not taking school dinners. The reverse was the case in the town where school meals were not satisfactory.

The diets of children whose mothers did not go out to work were, on the average, somewhat better than those whose mothers went out to work.

We are glad to record our appreciation of the very efficient way in which the staff of the Wartime Social Survey did the survey. We record with pleasure our grateful thanks to Dr. J. L. Burn and the late Dr. D. M. McKechnie and other staffs for their unstinted assistance and co-operation in every possible way. We wish also to thank Dr. Neil Jenkins, Dr. L. P. Kendal, and Mr. I. F. Langmuir for the ascorbic acid determinations, and Mr. H. U. Thompson for laboratory accommodation and assistance.

Better provision for the help and care of the unmarried mother and her child, through co-operation between local authorities and existing voluntary agencies, is recommended by the Secretary of State in a circular issued by the Department of Health for Scotland. The high death rate among illegitimate children was brought out in the report on infant mortality in Scotland by a subcommittee of the Scientific Advisory Committee, and last year (when the mortality was 108 per 1,000 illegitimate births) local authorities were asked by the Department to consider improvements for the care of illegitimate children. The problem has acquired new importance in view of the increased numbers of illegitimate births during the war years. If the unmarried mother is unable to stay in her parents' home local authorities could provide reliable guidance and help on such matters as accommodation, aliment, employment, foster-parents, and legal adoption. The statutory services which are available to all expectant and nursing mothers and to infants and young children are available to the unmarried mother and her child. The authority should "take positive steps" to set up a close liaison between the public health and the public assistance departments as problems are brought to light during the ordinary administration of public assistance. The most promising line of attack and the one likely to give the quickest results, the circular suggests, is "close and mutually sympathetic co-operation" between local authorities and voluntary agencies already dealing with the problem of the unmarried mother and her child.

REPORT ON NEARTHROSIS OF THE SHAFT OF THE HUMERUS FOR AMPUTATIONS ROUND THE ELBOW-JOINT

BY

LEON GILLIS, M.Ch.(Orth.)Liverp., F.R.C.S.Ed.
Senior Surgeon, Queen Mary's (Roehampton) Hospital, London

The loss of an arm, especially in the case of a manual worker, is a much more serious matter than the loss of a leg, and everything should be done to enable the sufferer to make use of whatever remains of it. Two alternatives offer themselves for this purpose: (1) the provision of an artificial limb, or (2) cineplastic operations (in suitable cases).

For many good reasons cineplastic surgery has not been popular in this country, and the almost universal trend has been to provide an artificial arm with fitments in the form of appropriate appliances for toilet, feeding, and work. In the majority of cases this has proved successful. There is, however, a marked difference in the success attained, depending on whether the amputation is above or below the elbow, the prosthesis for the latter being infinitely more useful. So much has this fact been impressed on us that every endeavour is made to save at least some inches of the forearm, and the limb-makers have succeeded in fitting useful limbs to short forearm stumps. Hitherto, arms which had of necessity to be amputated primarily just above the elbow-joint, through the joint, or immediately below the joint required reamputation at the site of election, which is 7 or 8 in. below the tip of the acromion, so as to provide enough space below the end of the humerus for the simple mechanism of the artificial elbow-joint.

The loss of often healthy skin, muscles, and bone in these reamputations caused me to wonder if more use could not be made of them, and the idea was conceived to construct a simple hinge-joint in the shaft of the humerus and so conserve the power of the muscles surrounding it and give a short secondary stump which would, to some extent, act as a forearm.

So far as one could see, nothing could be lost except some time. If the arthroplasty proved a failure, then the joint having been made at the normal site of election, reamputation could still be carried out without further loss of tissue than would have been the case had the normal reamputation been undertaken in the first instance.

Purpose of the Operation.—This is: (1) to conserve the muscular power of the flexors and extensors of the forearm and harness their power usefully; and (2) to make a joint in the shaft of the humerus so that there is about 4 in. of bone distal to the joint. Up to the present 24 operations of this type have been performed on 16 patients.

Problems Concerned in Making the Nearthrosis

1. *Prevention of Callus Formation and Subsequent Ankylosis of the Joint.*—It is interesting to note that fractures of the middle third of the humerus have a tendency to non-union. The treatment of the bone-ends and medullary cavity with bone-wax, we had hoped, would further discourage bony union, but in the first eight cases bony union was taking place and exuberant callus being formed. Over one hundred years ago Charles Bell wrote: "Scrape a bone and its vessels bleed; cut a bone and its granulations sprout up; break a bone and it will heal; cut a piece away and more bone will readily be produced; burn it and it dies."

From the eighth operation onwards we adopted the following methods to prevent callus formation and bony union: (1) We removed 1½ to 2 in. of the shaft of the humerus, *extraperiosteally*, at the proposed site of the new joint. (2) The bone-ends were fulgurized by electrocautery. (3) 10 to 15 g. of sulphanilamide powder was packed into the space between the bone-ends. Sulphanilamide in high concentration is said to inhibit phosphatase activity, which is intimately concerned with calcification. (4) The arm was immobilized in a straight plaster case for two to three weeks and muscle activity was discouraged at first.

2. *Provision of a Useful Range of Movement.*—Lateral instability is largely controlled by the hinge prosthesis, and is not so important as might at first appear. As regards the range of movement necessary to be of real value, we are advised by experts on artificial arms that in the case of a single arm amputation a range of 90°—that is, from the straight 180° to 90°—would be very valuable, but half this range would still be useful. Our last 10 cases have an active range of 90° and a passive range of a little more. In double arm amputations the important arc of movement is from 90° to 30°, so that the hand can be brought to the mouth. It seems unlikely that this could be achieved with the nearthrosis described without additions to the prosthesis. In general, the simpler the type of joint made the greater the range of movement. If only freedom of movement at the nearthrosis can be maintained, one can expect an increase in the active range owing to shortening and accommodation of the flexors, with improved muscle power and co-ordination.

3. *Provision of a Fulcrum.*—This is a problem, and crepitus and telescoping of bone-ends reduce the efficiency of the muscles acting round the new joint. However, the operation of removing 1½ to 2 in. of bone not only encouraged non-union but also enhanced the range of movement and eliminated crepitus of the bone-ends, which was sometimes irritating to the patient but never painful. Improvements contemplated in this respect include the trial of a simple compact vitallium hinge, the limbs of which consist of two short spikes which could be pegged into the medullary cavity of the bone-ends or metal caps to fit the bone-ends. This again has obvious theoretical advantages, but the hinge might soon become so closely invested in fibrous tissue as to "seize up."

Operative Details

Type of Case.—The operation is indicated in: (1) above-elbow amputations, where at least 4 in. of the shaft of the humerus below the insertion of the deltoid muscle still remains; (2) in through-elbow amputations; (3) in very short below-elbow amputations which cannot be fitted with a below-elbow prosthesis; (4) in cases of congenital absence of the forearm.

Pre-operative Treatment.—We think it is important to explain to the patient the nature of the operation and impress on him that his remaining muscles will be able to perform their own function again. He is taught to contract his muscles before the operation and to develop maximum power.

Operative Technique.—For the first 16 operations the incision used for exposure of the shaft of the humerus was a 3½-in. incision over the lateral intermuscular septum. The brachialis anterior and biceps were retracted forwards and the triceps retracted backwards. Sometimes the musculospiral nerve was seen. It, too, was retracted backwards. This incision was altered to a muscle-splitting posterior incision in the last eight operations because it was felt: (*a*) that, however carefully the operation was performed, a certain amount of weakness of the flexor muscles was inevitable; and (*b*) that an incision passing through the triceps muscle was of more value because extension was not so important and, in any case, is assisted by gravity. At first the periosteum of the humerus was exposed and incised. The humerus was sawn through and about half an inch of the shaft removed and the ends bevelled at an angle of 45° in front so as to allow maximum flexion (Figs. 1 and 2).

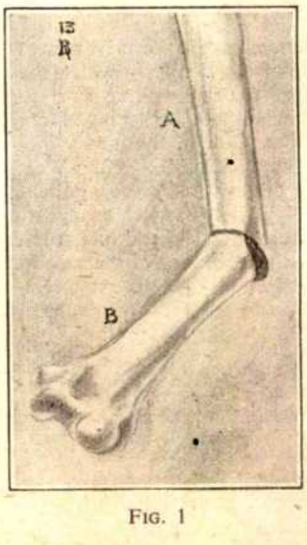

FIG. 1

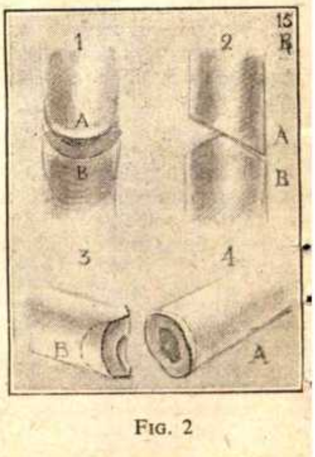

FIG. 2

The medullary cavity of the bone was curetted, the bone-ends were treated with Horsley's wax, and the medullary cavity was plugged with the wax. This has now been supplanted by liberal excision of the bone—i.e., at least 1½ to 2 in. of it—and fulguration of the bone-ends.

Post-operative Treatment

Originally the new forearm was put up in acute flexion, which was retained for 24 to 48 hours by a posterior plaster support. In the first six cases the patient began to contract his flexor muscles actively within 24 hours of the operation. Faradism was started on the third day. After three to four days the patient realized he had control of the distal end of the stump. A special plaster arm cage was supplied to keep the stump flexed and to improve flexor power. After one week he was allowed to leave the apparatus off for an hour in the morning and an hour in the afternoon, and graduated exercises were given. The new forearm could be flexed to a right-angle without interfering with the nutrition of the distal stump.

The revised post-operative treatment now starts about three weeks after the operation, when a straight plaster case in which the limb has been immobilized is removed. Apart from faradism, graduated exercises, and swimming, it is important to flex the stumps and bandage them with a figure-of-8 crepe bandage, which reduces the oedema, helps to stretch the triceps muscle, and allows the flexors to take up the slack. The patients also sleep quite comfortably with this figure-of-8 bandage, which is put on with maximum tension.

Up to the present it has not been necessary to interfere in any way with the retracted muscle or tendon ends which re-insert themselves in the fibrous mass of the amputation stump.

Case I

Pte. P., aged 34. Shell wounds of left arm and forearm on Oct. 24, 1944, in Holland. Amputation through the elbow-joint was performed the same day, and compound comminuted fracture of the upper third of the humerus treated by wound toilet and immobilization. By Jan., 1945, all wounds were healed and the fractures of the humerus were soundly united in good position. Despite the fracture and scarring, the arm muscles were well developed and powerful, the tendons of triceps, biceps, and brachialis apparently being firmly adherent to the end of the stump.

Operation, Feb. 1, 1945.—The shaft of the humerus was exposed through a 3½-in. vertical incision on the outer side of the lower third of the arm and by blunt dissection through the lateral intermuscular septum. The bone was divided 4 in. from the distal end with an electric saw. The ends of the bone were turned out into the wound and shaped to fit loosely one in the other. A hole was drilled through them and a steel wire passed through the hole to act as a pivot. All bone dust and chips were carefully removed from the wound, but no bone wax was employed in this case. A posterior plaster slab was applied, keeping the stump flexed to a right-angle.

After-treatment.—After 48 hours the slab was removed and active movements encouraged. The slab was replaced at night and when resting. About a week after operation a light hinged elbow cage was applied to the arm and movement was encouraged.

Progress since Operation.—The operation wound healed cleanly. After two weeks there was marked improvement in voluntary contraction, and the stump could be flexed actively through 45° from the straight. Considerable crepitus occurred on active movement, but surprisingly this caused no pain. One month after operation the range of movement remained the same, but there was marked improvement in power and control of the nearthrosis. Six weeks after operation, although accurate measurement was difficult, we had the impression that the range of movement was decreasing.

Second Operation.—Ten days later there was no doubt that the range of movement was diminishing, only a few degrees of active movement being then possible. Radiography revealed a well-marked sheath of callus around the bone-ends. It was plain that bony union was imminent. Operation was decided upon, and on March 26 the original incision was reopened. A spindle-shaped mass of callus was found surrounding the bone-ends and the wire which had been left in at the previous operation. The ossifying mass was chiselled and scraped away; the steel wire was then removed and the bone-ends trimmed. In an attempt to prevent further new bone formation the bone-ends were then treated as follows: The medullary cavity was curetted; the bone-ends were cauterized all over their exposed surfaces with a hot soldering-iron and an electrocautery. After this, bone wax was smeared over them and the medullary cavity plugged. The whole periosteal cavity was then thoroughly swabbed out with alcohol in the hope of still further inhibiting the osteoblastic cells in the periosteum. The wound was closed and a plaster slab applied, holding the stump flexed. This patient is now wearing a prosthesis flexing his new forearm to a right-angle, and has great muscular power. He does carpentry.

Case II

L/Cpl. B., aged 22, wounded in Holland on Nov. 20, 1944. On admission he presented a healed amputation stump of the left arm. Radiographs showed that the humerus had been sawn off immediately above the condyles. The muscles had evidently been sutured together over the bone-end, as a terminal pad of soft tissue could be moved voluntarily.

Operation, Feb. 22, 1945.—Humerus exposed (as described). The bone was divided with an electric saw and osteotome 4½ in. from the distal end. The bone-ends were in turn projected out of the wound and about 1/4 in. of bone trimmed off each. The upper end was then bevelled to a convex shape and the lower end excavated into a cup shape to receive it. Both bone-ends were smeared with Horsley's wax, and the medullary cavity was plugged with the same substance. No anchorage of any sort was attempted. A posterior plaster slab kept the lower fragment flexed at a right-angle.

After-treatment.—The slab was removed after 48 hours, and active exercise and faradism to the arm muscles were given. After four days an elbow cage was applied.

Progress.—Three weeks after operation the wound was soundly healed and muscle power and control were improving. The range of active movement was about 30° (i.e., from 180° to 150°). Considerable crepitus with overlapping of the bone-ends, was felt when flexion was carried out against resistance, but there was no pain.

Increasing limitation of movement necessitated a second operation on June 27, under the revised technique. The patient is at present wearing a prosthesis and is able to flex well to a right-angle. He is a farm labourer, and is pleased with the result.

Case III

Rfm. B., aged 24, had a traumatic amputation of the left forearm on Jan. 18, 1945, by shell-burst in Germany. Reamputation, with primary suture, was performed above the elbow-joint the next day at a field surgical unit. The amputation wound healed by first intention, and on admission he presented an arm stump of 11½ in. (from acromion to bone-end), with a soundly healed scar. The arm muscles were very little wasted, retaining good power of voluntary contraction, the cut end of biceps and triceps tendons being firmly adherent to the scar on the end of the stump.

Operation, March 2, 1945.—The shaft of the humerus was exposed as previously described. The humerus was divided transversely 3½ in. from the lower end with a Gigli saw (this has proved to be technically much the easiest and neatest method of osteotomy). The bone-ends were dislocated out into the wounds and a "step" was cut in the upper one, the lower one being bevelled anteriorly. The cut ends of the bone were treated with Horsley's wax and the medullary cavity was plugged with that substance. The bone-ends were then drilled from before backwards, and two stout silk sutures were passed through and tied so as to keep the bones in apposition, yet loosely enough to allow flexion and extension. A plaster slab was applied to keep the lower fragment flexed at a right-angle. After-treatment was carried out as in Case II.

Progress.—Two weeks after operation the wound was soundly healed and there was an active range of 40° flexion from the straight; in this case there appeared to be less instability of the joint. Passive flexion to a right-angle was possible, but this could not be achieved by the patient's own efforts.

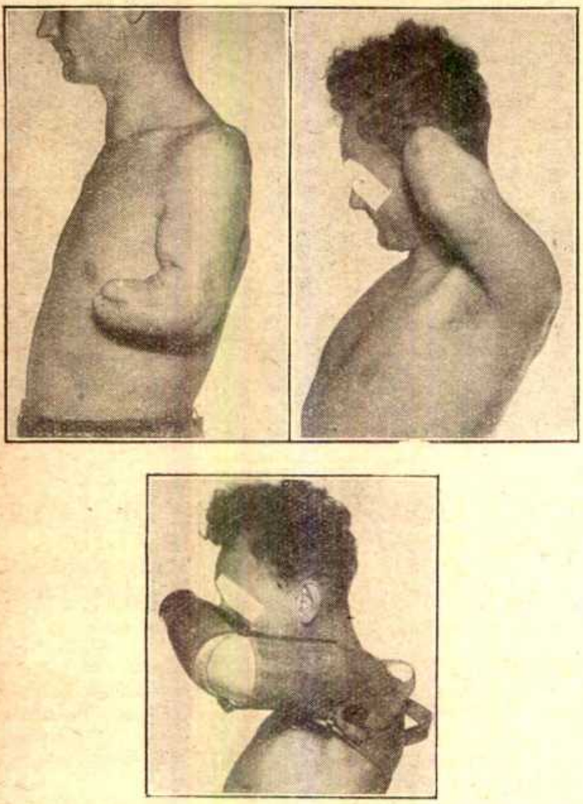
Increasing limitation of movement necessitated a second operation on June 28, under the revised technique. The patient is at present wearing a prosthesis and is able to flex well to a right-angle.

Case IV

Spr. L., aged 25, wounded by mortar in Holland, Nov. 3, 1944. Amputation through the upper third of the left forearm was performed on Nov. 5, the flaps being left open owing to gross sepsis. The remains of the head and shaft of the radius were removed after two weeks; the stump of the ulna separated as a sequestrum a few weeks later, leaving the olecranon and coronoid notch intact. By the end of Feb., 1945, the stump was almost healed. A few degrees of movement were present in the olecranon stump, but a forearm prosthesis was out of the question.

Operation, March 14, 1945.—Incision and exposure as before. The shaft of the humerus was divided 4½ in. from the distal end with the Gigli saw. In this case the bone-ends were bevelled at a more acute angle, the object being to facilitate flexion even at the expense of loss of full extension. Holes were drilled laterally through each bone and a double stout silk ligature was passed through them, which, when tied, formed artificial lateral ligaments and served to anchor the bone-ends together. The bone-ends were treated with wax as previously described and the wound was closed.

Increasing limitation of movement necessitated a second operation on May 24, under the revised technique. The patient is at present wearing a prosthesis and is able to flex well to a right-angle (Figs. 3-5). He is back at work driving a tractor.



FIGS. 3 to 5.—Photographs showing amount of flexion obtained with the stump, the temporary prosthesis worn, and the useful movements accomplished.

Case V

Lieut. L. G., aged 22, wounded in Italy May 29, 1944. Arm amputated through elbow the same day. This was a through-elbow amputation soundly healed, with a terminal scar.

Operation, April 5, 1945.—Through a 3½-in. incision over the lateral intermuscular septum the humerus was exposed. On this occasion the periosteum was not raised, but an aneurysm needle was passed round the bone *outside the periosteum*, and with a Gigli saw the bone was divided. Half an inch of bone was cut off each end. The distal end was slightly bevelled in front and the medullary cavity curetted. The ends were then treated with the electrocautery. The medullary cavity was plugged with wax and the bone-ends replaced. The arm was then put up in full flexion with a plaster slab.

Increasing limitation of movement necessitated a second operation on June 12 under the revised technique. The patient is at present wearing a prosthesis and is able to flex well to a right-angle. He is back at work farming.

Conclusion

Up to date I have performed 24 operations, the first 16 through the lateral approach described. The last 8 have been performed through a posterior muscle-splitting incision. The bone-ends have been fulgurized with diathermy after removal of at least 1½ to 2 in. of humerus. The cavities resulting between bone-ends have been packed with sulphanilamide powder. The first eight cases have been operated on twice, either for removal of exuberant callus or for removal of the wire or the twisted silk, which had become involved with the callus and caused the new joint to "seize up."

In 10 of these cases the new forearm can be actively and painlessly flexed to a right-angle. The remaining 6 have varying degrees of active flexion, which is still improving. Passive flexion in all the cases can be increased beyond the range of active flexion. All these patients have good position sense and can manipulate their new forearms so that they can either scratch the back of the head or bring the stump to the mouth. The nutrition of the distal stump has not been interfered with. The point which has been established is that the arm muscles are capable of acting on a new joint in the humerus to effect and control a useful range of movement. The new forearm can be fitted with a very useful below-elbow prosthesis.

At present not all the problems referred to in this paper can be answered, and their satisfactory solution must await further study. In the meantime, the above series of cases may serve to direct attention to this work, and we hope will bring forward suggestions for solving those problems. Some possible uses of this operation include: (1) to provide a controlled "forearm" stump for amputations as described; (2) to enable a forearm prosthesis to be fitted to very short below-elbow amputations, the elbow being arthrodesed; (3) to use the short end of the new forearm as a cineplastic stump.

Summary

A new operation is described for making a joint in the shaft of the humerus for cases of amputation near the elbow-joint. The muscles are able to act over this joint with useful power and without pain. Work is in progress to try to improve the actual joint and to overcome the technical difficulties.

I should like to thank Sir Walter Haward, O.B.E., Director-General of Medical Services, Ministry of Pensions, for permission to publish this article, which does not necessarily represent the view of that Ministry; Major-Gen. Brooke Purdon, D.S.O., O.B.E., *M.C.*, medical superintendent, Roehampton Hospital, for his enthusiasm and co-operation; and all my colleagues on the staff of Roehampton Hospital who have so kindly assisted in this work.

AGRANULOCYTOSIS AFTER SULPHONAMIDE SENSITIZATION: PENICILLIN THERAPY: DEATH FROM PS. PYOCYANEA SEPTICAEMIA

BY

J. D. CAMERON, M.B., Ch.B.

AND

J. R. EDGE, M.B., Ch.B.

Medical Officers at an E.M.S. Hospital

This case is reported because of the unusual circumstances of onset, and in view of the recent interest centred round *Ps. pyocyanea* infection and penicillin therapy.

Case Report

An otherwise healthy soldier, aged 19, was admitted to hospital on Nov. 14, 1944, with extensive scarring of the left forearm which had resulted from a gunshot wound on Sept. 19. Between Sept. 19 and 22 he had received sulphanilamide 10 g. and sulphadiazine 35 g., with no signs of intolerance. On admission the wound was completely healed except for a small dry scab. On Nov. 24 the patient became ill, and complained of a sore throat. On examination a grossly enlarged and inflamed right tonsil was found; temperature 101.6°. Sulphathiazole, 1 g. 4-hourly, was started.

Nov. 26.—Temperature 102°. A throat swab was reported to grow pneumococci. The throat was much improved, but the wound now showed early inflammation.

Nov. 28.—Temperature 101.6°. Inflammation of tonsil subsided and patient stated he felt much better. The wound showed a surrounding area of induration with inflammation, and superficial vesiculation in the centre. Sulphathiazole discontinued (total 15 g. in 4 days).

For the next two days the patient stated he felt quite well, but he continued to run a temperature of 101-102°.

Nov. 30.—Temperature 103°. Wound sloughing; axillary adenitis. Sulphapyridine 1 g. 4-hourly started.

Dec. 2.—Temperature 102°. Wound showed a large central slough; a swab from the wound was reported to grow (1) penicillin-sensitive *Staph. aureus*, (2) penicillin-insensitive *Ps. pyocyanea*. Penicillin, 15,000 units intramuscularly 3-hourly, was started.

Dec. 3.—Patient was flushed and ill. Temperature 103.4°; pulse 120. A waxy pallor of the skin was noted. The throat was normal, but breaking down of the wound was extending in spite of treatment. Blood count: R.B.C., 3,500,000 per c.mm.; Hb, 65%; W.B.C., 2,000 (80% lymphocytes). Sulphapyridine was discontinued (14 g. total in 2 days). Pentnucleotide, 10 c.cm. intramuscularly 6-hourly, was started.

Dec. 4.—Temperature 104°; pulse 120. W.B.C., 1,000 per c.mm. (lymphocytes 900, polymorphs 90, myelocytes 5, eosinophils 5). Two pints of fresh blood were transfused, and penicillin, 20,000 units 3-hourly, was given by drip in addition to the I.M. course.

Dec. 5.—The throat showed ulceration for the first time and the breath had rapidly become extremely fetid. The patient went rapidly downhill and died in coma at 3 p.m., the temperature having become subnormal five hours previously. Two separate blood cultures showed profuse growths of *Ps. pyocyanea.*

There was never any other evidence of sulphonamide intolerance such as rash, conjunctivitis, joint effusion, or haematuria.

Bacteriological Examination.—The *Ps. pyocyanea* from the blood culture was found to grow in broth with a concentration of 3,000 units of penicillin per c.mm. Tested against sulphanilamide, sulphathiazole, sulphamezathine, sulphadiazine, sulphapyridine, and sulphaguanidine, normal growth occurred in concentrations of 50 mg. per c.cm. (i.e., concentrations higher than those usually obtained in the blood).

Rosenthal and Vogel (1939) and Sweeney and Allday (1940) draw attention to the dangers of repeated sulphonamide therapy. Erskine (1942) and Park (1944) believe that agranulocytosis is a result of sensitization and not a toxic effect. Nixon, Eckert, and Holmes (1943) treated with the same drug three cases of agranulocytosis following sulphadiazine, and all three recovered. They believe that the neutropenia is transient, and that the continued use of the drug controlled the infection until the marrow recovered.

The lethal capabilities of *Ps. pyocyanea* even in the absence of agranulocytosis are emphasized by the following reports:

Botterell and Magner (1945) describe 11 cases of meningitis due to *Ps. pyocyanea,* with 9 deaths. Penicillin, sulphadiazine, and sulphapyridine were ineffective in the nine fatal cases. Three cases were given repeated intravenous injections of sodium iodide, and two recovered.

Evans (1945) describes 2 fatal cases of *Ps. pyocyanea* septicaemia following spinal analgesia.

Roberts, Tubbs, and Bates (1945) describe a case of venous thrombosis complicating a penicillin drip in a case of pulmonary actinomycosis secondarily infected with *Ps. pyocyanea.* The thrombus became infected with that organism, and a fatal pyaemia resulted.

The relative infrequency of *Ps. pyocyanea* infection in agranulocytosis is shown by Kracke and Parker (1934), who analyse 74 positive blood cultures out of 469 cases, the other cases being either negative or not stated. *Ps. pyocyanea* was grown in only 3 cases; 32 were streptococcal, 8 staphylococcal, and 8 pneumococcal, and the remaining 23 were from the coliform group. Reference is also made by these writers to a German series with one case of *Ps. pyocyanea* infection out of 23 cases. The causes of the agranulocytosis are not stated, but sulphonamides were not in use at that time.

Discussion

Our patient originally had 10 g. of sulphanilamide and 35 g. of sulphadiazine in four days with no signs of intolerance. After an interval of 62 days he received 15 g. of sulphathiazole over 4 days, and two days later 14 g. of sulphapyridine over 2 days. No white cell count was made during the original sulphonamide therapy, and it is regretted that one was not undertaken earlier in the second course. On looking back it appears that the neutropenia developed soon after starting the sulphathiazole, and that the breaking down of the wound must have been secondary to a deficiency of leucocytes. The long interval of 62 days between the courses of sulphonamides, and the early onset of symptoms during the second course, would suggest that sensitization was the mechanism in this case.

The agranulocytosis was treated with pentnucleotide, 70 c.cm. in 2½ days, and penicillin, 360,000 units I.M. and 120,000 units I.V. in 3 days. The effect of crude liver injections was to be tried, but a suitable preparation was not available in time.

When the diagnosis of agranulocytosis was established it was reasoned that penicillin would be of value in controlling the infection until the marrow had time to recover. The penicillin controlled the staphylococcal infection in the wound, but the *Ps. pyocyanea* invaded the blood stream and caused death. The continuance of sulphonamide therapy as suggested by Nixon *et al.* would in the presence of this resistant organism have been useless.

Although *Ps. pyocyanea* septicaemia has been described in agranulocytosis, no report of its occurrence in agranulocytosis following sulphonamide therapy has been found in the literature. Although local infections with *Ps. pyocyanea* are usually of little importance, systemic and meningeal infections are a menace owing to the lack of efficient methods of treatment. Treatment with sodium iodide appears to warrant further investigation.

Summary

A tragic case of agranulocytosis after sensitization to sulphonamides is described, emphasizing the dangers of repeated sulphonamide therapy.

It is suggested that penicillin in most cases of agranulocytosis will control the infection and so give the marrow time to recover. In this case death resulted from a *Ps. pyocyanea* septicaemia.

Our thanks are due to Dr. R. Clive Walker, medical superintendent, Highroyds Emergency Hospital, for permission to publish this case; and to Dr. C. J. Young, Bradford Royal Infirmary, for all the bacteriological investigations, and also for help in preparing the paper.

ACUTE YELLOW NECROSIS OF THE LIVER FOLLOWING TRILENE ANAESTHESIA

BY

K. N. HERDMAN, M.A., M.D., D.A.
Major, R.A.M.C.(T.); Specialist in Anaesthetics

The possibility of acute yellow atrophy developing as a sequel to chloroform anaesthesia has for long been taught, and this distressing misadventure has been emphasized as one of the lethal potentialities of chloroform, so daunting the tyro and, in some cases, making even the experienced chloroform administrator forsake his old favourite.

Despite points of resemblance chemically and pharmacologically between chloroform and trichlorethylene which might lead one to expect some similarity in their sequelae, acute yellow atrophy has not up to the present been regarded as a risk of trilene anaesthesia, nor, so far as we are aware, has a case been recorded. The following case history is presented on account of its unique nature and bearing in mind the oft-repeated plea for a fuller and more candid discussion of anaesthetic misadventures.

Case History

On March 4, 1945, a Dutch officer aged 28 sustained deep cordite burns of the face and hands, for which he received treatment in two other general hospitals in B.L.A. The following relevant facts are taken from their records:

March 13.—Deep burning of all four eyelids—already very septic.

April 14.—Sepsis finally got under control. Patch grafts applied to residual raw areas on face, forehead, and hands. Lids healed.

May 28.—He was transferred to this hospital to be under the care of an eye specialist, from whose records the remainder of this history is extracted.

"There was severe cicatricial ectropion of all four eyelids—the left worse than the right—and the corneae were exposed. Operation was indicated to save the eyes from destruction by corneal ulceration. Left eye worse than right—to be operated on first.

June 1.—Operation under general anaesthesia (pentothal followed by gas, oxygen, and trilene). Left eyelids and outer canthus: Dissection of scar tissue; tarsorrhaphy; split-skin graft sutured in position over raw areas.

Except for a complaint of tiredness and drowsiness, convalescence ran a normal course for the first four days.

June 5.—Abdominal pain with 'guarding' in epigastrium; vomiting of food material; liver enlarged.

June 6.—Liver 3 in. below costal margin; tenderness over liver ++; skin and conjunctivae yellow; bile salts in urine. T. 99°; P. 110; R. 20.

June 7.—More deeply jaundiced. Liver smaller—1½ in. below costal margin. T. 100°; P. 115; R. 20.

June 9.—Drowsy. Graft dressed; taken 100%.

June 10.—Hiccups; drowsy and uncommunicative; tongue and lips dry. Urine: acid; albumin and bile +; occasional granular casts. Icteric index, 114. Blood urea 34 mg., blood sugar 115 mg. per 100 c.cm. Abdomen distended with flatus; little result from flatus tube or turpentine enema.

June 11.—General condition deteriorating.

June 12.—Died at 08.15 hours."

The patient was treated with liberal glucose and fluids—at first orally and later by intravenous glucose-saline drip, alternating with plasma. Towards the end he received 20 units of insulin b.i.d.

Anaesthetic History

Pre-operative Condition.—Patient fit and well. He was keen to undergo this operation, though immediately before it he appeared somewhat apprehensive. Heart and lungs normal.

Premedication.—Morphine 1/4 gr. with hyoscine 1/100 gr. one hour before operation.

Anaesthesia.—Induction: Pentothal (freshly prepared) 0.8 g. intravenously. Intubation: Nasal route—blind. Maintenance: Gas-and-oxygen passed over trilene, using Boyle field-pattern apparatus (no CO_2 absorber attached). Duration, 4½ hours. Total quantity of trilene, 2 oz. Anaesthesia was smooth throughout and the patient was kept fully oxygenated. There was no tachypnoea, and no pulse irregularity was observed. The endotracheal tube was removed on the table, by which time the cough reflex was brisk. Trilene from the same bottle was used in the same apparatus for other patients with no untoward effects.

Necropsy Report

Abdomen.—Free bile-stained fluid in peritoneal cavity—about 2 pints. Bladder full, distended with bile-stained urine. Numerous large subendothelial haemorrhages involving the whole gut and mesentery. Parietal peritoneum showed marked engorgement of stellate vessels.

Spleen.—Soft, and enlarged to twice normal size.

Liver.—About two-thirds normal size. Cut section showed typical features of acute diffuse yellow necrosis as a mottling of red and yellow areas. Microscopically: Central, mid-zonal, and peripheral necrosis, with scanty regeneration of bile ducts. The liver cells had entirely disappeared except for scanty islands of necrotic hepatic cells peripherally arranged.

Kidneys.—Congested and oedematous. Capsule stripped easily. Demarcation of cortex from medulla less obvious than normal. Blood dripping from cut section. Otherwise no obvious macroscopic lesion.

Heart.—About 6 oz. of clear straw-coloured fluid in pericardium. Small petechial haemorrhages under visceral pericardium. Heart showing terminal right-sided dilatation. Myocardium flabby. No other abnormality detected.

Lungs.—A little free fluid in pleural cavities. Large subendothelial haemorrhages under visceral pleura. Congestion of parietal pleura. Marked engorgement of basal lobes of both lungs. Trachea, bronchi, and bronchioles showed congestion, but no other abnormality.

Conclusions.—(1) Acute yellow necrosis of liver. (2) Ascites. (3) Subendothelial haemorrhages.

Commentary

An endeavour must be made to determine whether the fatality is to be regarded as attributable to an idiosyncrasy of this patient towards trilene or whether an error of judgment was made in using trilene as the main anaesthetic agent.

The patient's history of burns and sepsis immediately suggests the possibility of liver damage having occurred; but the burns, though deep, involved a very small area, and it is recorded that sepsis had been finally cleared up fully six weeks before operation. It would appear justifiable to assume that enough time had elapsed to allow of full recovery of hepatic function.

The operation was a prolonged one, but the total quantity of trilene used—2 oz.—would not appear to be excessive, and suboxygenation was not allowed to occur. Some additional strain may have been thrown on the liver by the use of both pentothal and trilene, though hitherto we have used this sequence as a routine. As this patient belonged to the Netherlands Army, the question arose whether his liver might have suffered as a result of malnutrition during the German occupation; but his widow, on questioning, affirmed that his diet was fully adequate throughout that period. Perhaps it is worth considering whether a patient who is to undergo a prolonged anaesthesia with trilene as the main agent should be prepared as for chloroform—by intensive administration of glucose in the pre-operative and immediate post-operative periods.

Trilene has now become firmly established as an anaesthetic agent of considerable value, and up to the present remarkably few untoward sequelae have been reported, so long as the CO_2 absorption technique is avoided. (In this hospital during the past 10 months trilene has been used as the main anaesthetic agent in 333 cases. One fatality occurred in this series, the operation being laminectomy of the fourth cervical vertebra for removal of a fragment of metal which had practically destroyed the spinal cord at that level. Only one-half of the diaphragm was in action, and this patient, who weighed 16½ stone, was regarded as a desperate operative and anaesthetic risk. Apart from this one case no untoward sequelae have occurred except for very occasional and transient nausea or vomiting.) Perhaps this has tended to lull us into a false sense of security, and, while it is not for a moment suggested that the fatality reported here should lead us to abandon this useful agent, it would appear that perhaps we should exercise a little more care than has been our custom in the selection of our cases and in safeguarding the liver by ensuring full glycogen reserve both before and after any prolonged administration of trilene.

Summary

A case is reported in which death occurred from acute yellow necrosis of the liver 11 days after a prolonged trilene anaesthetic.

The main necropsy findings are recorded.

Some aetiological factors are considered, and the suggestion is made that liberal administration of glucose should become a routine practice, both before and after any prolonged administration of trilene.

I wish to record my thanks to Col. R. G. Shaw, *M.C.*, for permission to publish this case; to Lieut.-Col. J. W. Osborne, R.A.M.C.(T.), Lieut.-Col. D. H. Young, O.B.E., R.A.M.C.(T.), and Major H. B. Stallard, M.B.E., R.A.M.C.(T.) (eye specialist), for the clinical records; and to Major R. Winston Evans, R.A.M.C.(T.), for the necropsy report.

Medical Memoranda

Strangulation of Foetal Intestine before Term

The following maternity case came under my observation with some interesting features which warrant further discussion.

A multipara 4, aged 31, was admitted to the Maternity Department for her confinement owing to unsuitable home surroundings. She was rather feeble-minded. There was nothing relevant in her obstetric history, and progress of pregnancy was uneventful. B.P. 135/90, fundus 39 weeks, position R.O.A., and foetal heart heard.

At 3 p.m. next day labour began, membranes rupturing half an hour later, and the foetal head was born at 5 p.m., but the shoulders failed to be delivered. She was put under a general anaesthetic, and the cause of obstruction was found to be a contraction ring almost encircling the child's trunk just below the 9th rib. This was "ironed out" with some difficulty and the birth completed. There was nothing to my knowledge in the circumstances to favour the presence of such a ring. Moreover, the stillborn child was found to have gross ascites.

At necropsy a large quantity of semi-opaque golden-brown fluid containing brownish flakes was found free in the child's peritoneal cavity. A greenish-black mass was seen lying transversely just above the umbilicus, and was adherent at one point on the left side to the parietal peritoneum. On gentle separation from the adherent coils of intestine this mass was found to contain a loop of small gut which had obviously been strangulated by an omental band running downwards from the transverse colon to be attached near the root of the mesentery of the small intestine. The continuity of this loop had apparently dissolved with the extrusion of meconium between the layers of its peritoneal covering. The specimen can be seen at the Museum of the Royal College of Surgeons of England. I presume that this strangulation must have occurred some time before term, and an aseptic necrosis of the strangulated loop had resulted. There was nothing abnormal in the remaining contents of the abdomen, nor was there any evidence of peritonitis.

Probably the death of the child was caused by the difficulty in effecting delivery, but it obviously would not have lived any length of time had it been born alive.

I wish to thank the medical superintendent for his criticism and kind permission to publish the case.

A. H. Esmat, L.R.C.P.&S.Ed.,
Resident Surgical Officer, County General Hospital, Worksop.

Improved rates of pay in Scotland for nurses in mental institutions are recommended in the fourth report of the Taylor Committee just published. An Exchequer grant of 50% of the increased expenditure will be paid to all local and hospital authorities adopting the recommendations, which provide, among others, for new salary scales. These scales came into force as from April 1, 1945, but provision is made for the payment of arrears from April 1, 1943. A 96-hour fortnight and twenty-eight days' holiday a year with pay are other recommendations.

Reviews

A TEXTBOOK OF PATHOLOGY

A Textbook of Pathology. Pathologic Anatomy in its Relation to the Causes, Pathogenesis, and Clinical Manifestations of Disease. By Robert Allan Moore, Edward Mallinckrodt Professor of Pathology, Washington University School of Medicine, St. Louis. (Pp. 1,338; 513 illustrations, 34 in colour. 60s.) London and Philadelphia: W. B. Saunders Company.

This textbook is an important addition to pathological iterature. The author has made a determined and successful effort to correlate the aetiology of disease and its structural accompaniments with recent developments in physiology and biochemistry on the one hand, and with clinical signs and symptoms on the other. In spite of this, the basic facts of morbid anatomy and histology are generously and faithfully recorded. The style is crisp and direct, the book is packed with information, and covers a remarkably wide field; it is bulky but far from unwieldy, and is well documented. The large majority of references are to articles written in English. This, the author explains, is "a frank and practical acknowledgment that few Americans read any other language except their own." The illustrations are superb; many are in colour and well reproduced. They are not limited to photomicrographs and morbid changes in organs; many of them are clinical, and there are several excellent radiographs; a few are historical, these being well chosen and skilfully scattered through the text.

To the advanced student who has grasped the general principles of pathology and has some knowledge of the problems of infection and immunity this book will undoubtedly prove to be of great service, as well as being stimulating and refreshing. It may be "strong meat" for the elementary student in this country just beginning his crowded and top-heavy clinical curriculum.

The attempt made in this book to correlate abnormality of structure with basic biological science and clinical observation s a sign of the times which future authors of British textbooks cannot afford to disregard.

RESEARCH ON SCABIES

Human Guinea Pigs. By Kenneth Mellanby. (Pp. 96. 4s. 6d.) London: Victor Gollancz. 1945.

t is uncommon to find romance and science wedded together, but Major Kenneth Mellanby seems to have succeeded in his very readable book *Human Guinea Pigs,* in which he records he story of the work at the Sorby Research Institute in Sheffield.

During and some time after the war of 1914–18 scabies ssumed epidemic proportions, and it seemed likely that history would repeat itself. In the checking and (as it may eem) in the control of the epidemic the Sorby Institute and ts human guinea-pigs, who were all conscientious objectors, can claim an honourable part. Major Mellanby's investigations are so well known to medical readers that no more need here be said than to recall that he showed the relative unimportance of bedding and clothing as a source of infection to others—which must have saved the public health authorities both time and money—and that he set the seal of official approval on benzyl benzoate as a sarcopticide. This was not everything, or as a sort of scientific by-product dietetic experiments were lso carried out, providing valuable information on, for xample, calcium metabolism.

Human Guinea Pigs is written for the layman, successfully avoiding the so-called scientific jargon which, because it is not lways understood, often misleads. The author also discusses he problem of the conscientious objectors, to whom he pays ribute for their zeal and co-operation in an environment where hey were encouraged and sympathetically treated.

In this account of the Sorby Research Institute Major Mellanby has provided a very human document, quite apart rom its professional interest and its record of a considerable achievement.

THE HOSPITAL AT WORK

The Hospital in Modern Society. Edited by Arthur C. Bachmeyer, M.D., and Gerhard Hartman, Ph.D. (Pp. 768. $5.00 or 28s.) New York: The Commonwealth Fund; London: Oxford University Press.

This is an unusual kind of book. It might claim to be an encyclopaedia of all matters affecting hospitals, but its information is conveyed in articles chosen from various publications, and their style is much less formal than one expects to find in an encyclopaedia. It would be difficult to mention any aspect of hospital life which is not dealt with here by a well-known authority. The compilers of the book say that it is intended for (1) hospital administrators, (2) the department head, (3) the student of hospital administration; and they go on to say that each article was "chosen for its judicious analysis of a problem, and because it stimulated thought on that problem regardless of the view of the editors, and at times in contradiction with opinions expressed in other articles." There are 145 articles by 98 authors. The book's claim to be encyclopaedic is strengthened by the fact that each chapter ends with copious "references for further reading."

It is impossible in the space at the reviewer's disposal even to mention all the subjects dealt with, but a good example of the book's quality and variety may be found in the first chapter, on "The History of Hospitals." This begins with an article by Dr. S. Goldwater, who deals in an attractive way with the motives underlying the establishment of some of the earlier hospitals. The second part, by Dr. Faxon, is learned and full of interesting detail. For example, it mentions an inquiry into the hospitals of Paris in 1788 which showed a yearly mortality of 6 to 12% among the surgeons and attendants, whereas, the reporter says, "it should not ordinarily exceed 3%." The chapter on "The Hospital, the Family Doctor, and the Patient," by Dr. Goldwater, though dealing mainly with American problems, shows once more that these are the same all the world over. The author protests against the too-prevalent idea that the United States is a country where everybody is well off and therefore able to pay for his medical care. As a proof that this is not so he shows the steady growth of group practice attached to hospitals, many of them now including domiciliary attendance. He is a firm believer in keeping the family doctor in association with hospitals, because not only would this be of benefit to the patient but "the physician who enjoys a proper institutional association avoids the danger of being careless and superficial in his clinical methods." Dr. W. H. Spencer in "Hospital Organization and Management" thinks that all privately supported institutions in the United States, including hospitals, will have much more financial difficulty in the future owing to a decrease in the benefactions they have had from wealthy people, whose numbers and incomes are steadily declining. Among the urgent financial difficulties of the hospital is the question of the proper payment of its administrative staff. Hitherto there has been a tacit assumption that the personnel, like the doctors, are partly paid by a feeling of satisfaction in participating in the relief of suffering humanity. He thinks this assumption unfair, and that in any case it is steadily being undermined by vocational organization among the hospital subordinate staffs.

There are contributions on "Medical Staff Organization and Relationships," "Pharmacy," "Medical Records," "Admitting and Discharge," "Legal Aspects," "Construction of Hospitals," "Hospital Purchasing," "Laundry Management," to mention only a few; and the book ends with chapters on "Group Hospital and Health Insurance" and "Public Health."

This brief review of a readable and important book will, it is hoped, induce many hospitals to put a copy on their shelves. Nobody interested in hospital work could fail to find in it stimulus, instruction, parallels, and ideas as worthy of consideration here as in the U.S.A.

EMBRYOLOGY FOR MEDICAL STUDENTS

A Class Book of Practical Embryology for Medical Students. By P. N. B. Odgers. (Pp. 63; illustrated. 7s. 6d.) London: Oxford University Press.

The study of serial sections of embryos at different stages of development is greatly helped by explanatory drawings and diagrams, such as have been assembled by Dr. P. N. B. Odgers, Reader in Human Anatomy in the University of Oxford, and published under the title *A Class Book of Practical Embryology* *for Medical Students.* The drawings have been made by Miss A. F. Arnott from transverse sections of 6-mm. and 10-mm. pig embryos, and comprise typical cross-sections illustrating two important stages in the development of the heart and the adjacent blood vessels, nerves, and neighbouring organs, with explanatory notes; these are supplemented by three diagrams indicating the position of the corresponding parts when seen in sagittal or coronal section. In order to keep the drawings simple no attempt has been made to portray details in the structure of the various tissues, an arbitrary method having been adopted which serves to distinguish clearly nerves, vessels, tubes lined with epithelium, and such organs as the liver. Only the more important vessels and nerves have been delineated, though some of these of practical importance, such as the phrenic and recurrent laryngeal nerves, which one would have liked to see indicated and labelled, have been omitted.

The book in its present form is naturally limited in scope, but it will serve as a most useful and reliable guide for the recognition of the parts corresponding to the drawings when studying actual sections under the microscope, and it can be strongly recommended for this purpose.

Notes on Books

In six lectures to ward sisters on *Temperament, Character and Personality*, forming part of a course organized by the Royal College of Nursing, Mrs. N. MACKENZIE has given a fair presentation of normal psychological processes. In the first three she deals with the subject in a general way, explaining terms and showing how instinct and emotions are integrated into sentiments. In the last three she deals with the special aspects presented by the patient, the student nurse, and the ward sister herself. Though these lectures are necessarily incomplete, and perhaps oversimplified, it is refreshing to find that such information is being given to nurses, whose training in the past has been so conspicuously lacking in the psychological approach. If it could only be realized how much the comfort and well-being of the patient depend on the correct psychological approach of the nurse, and that every woman is not capable of this by intuition, we might look for more of this very necessary teaching. It is to be hoped that every nurse will not only read but study and take to heart these lectures, which have been published in the *Nursing Times*, and, if hospital physicians and surgeons could be sure that they themselves appreciated all that Mrs. Mackenzie is trying to teach, much good would ensue.

Positioning in Radiography, by Miss K. C. CLARK, is a superb book on radiography now in its fourth edition, and well deserves the high reputation it has earned in the radiological world. It is designed particularly for radiographers, but there can be few radiologists who will not learn something from it; most will learn much. The photographs of the subject, the skiagrams, and the diagrams are all of the highest quality, and the print and paper remind one of the happy days when books were books. If there be any *x*-ray diagnostic departments that do not possess a copy of this work, let them buy one quickly. Seventy-five shillings could hardly be better spent. The publishers are Heinemann Medical Books Ltd.

Practical Physiological Chemistry for Medical Students, by G. M. WISHART, D. P. CUTHBERTSON, and J. W. CHAMBERS, of the Institute of Physiology, Glasgow University, first appeared in 1936; a third and revised edition has now been published at 7s. by John Smith and Son (Glasgow), Ltd. The book is designed to present a course of practical chemical physiology to large classes of students whose time is limited to two-hour periods. The clinical aspect is stressed both in the choice of material and in the general treatment of the subject.

We have received from the National Institute for Research in Dairying, Shinfield, near Reading, a copy of *Advisory Dairy Bacteriologists*, being papers published from 1925 to 1943, edited by Mr. H. BARKWORTH. These reprints are grouped under three main headings: clean milk production, bacteriology, technology—and there is a foreword by Dr. A. T. R. Mattick. The pamphlet ends with eight pages of references, an index, and a list of centres and officers. It was in 1925 that advisory dairy bacteriologists were appointed to serve in the various provinces into which the country was divided. These officers were usually attached to the agricultural faculties of universities and to agricultural colleges.

An eighth edition of the late Mrs. J. LANGTON HEWER'S pamphlet *The Baby of To-day: First Principles in his Management*, revised by Dr. M. Scott-Brown, has been published by John Wright and Sons Ltd., of Bristol, at 1s.

The U.S.S.R. Society for Cultural Relations with Foreign Countries has issued from Moscow, as a 30-page cyclostyled document, No. 5 of the *Medical Chronicle* for May, 1945, being a special issue on the Academy of Medical Sciences of the U.S.S.R. The copy received from the Embassy in London may be seen at the library of the B.M.A.

Preparations and Appliances

AN AID TO TRANSFUSION

Dr. W. D. LINSELL writes from Cambridge:

The accompanying diagrams and photograph show a small piece of simple apparatus designed to assist transfusion practice. The inferior quality of much of the wartime adhesive strapping used in transfusions, with its tendency to work loose on the slightest movement of patient or apparatus, led me to evolve this simple appliance, which gives really rigid clamping of transfusion tubing to the arm or leg.

The procedure is simple: the transfusion is set up and the webbing strap passed round the arm and the splint, the rubber tube is placed in the open jaws, and these are clamped firmly on to the tube by simply pulling the strap tight. All rotation, wriggling, and pulling or pushing of the tube and consequent needle displacement are eliminated, except with the use of extreme force.

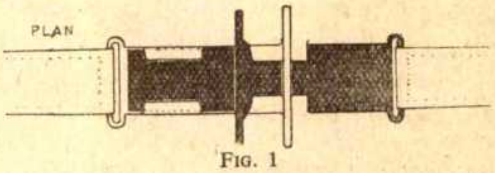

FIG. 1

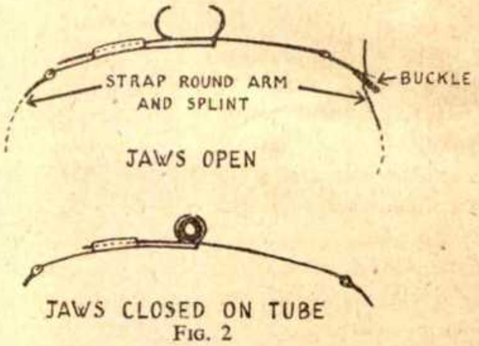

FIG. 2

The apparatus has been found to be of value in any cas where transfusions are subject to movement and violence; i would, I feel, have been of value on the battle fronts wit stretcher cases; it has been found that much "cutting down" on veins and tying in of cannulae is avoided where long-standin transfusion is required.

The photograph shows a leather strap; this has since bee replaced by webbing. The whole apparatus can be boiled.

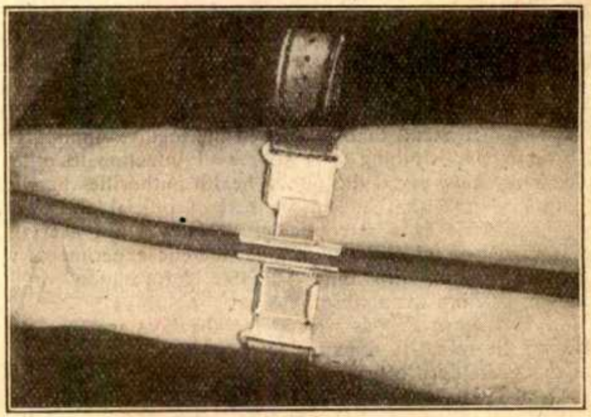

FIG. 3

I wish to thank Dr. Paul Sherwood and his colleagues Hill End Hospital, St. Albans, for trying out the apparatu and for helpful advice; I also wish to thank Mr. W. J. Harri of Messrs. Bailey and Son, Ltd., Oxford Street, W.1, for h kind co-operation in the manufacture of the improved patter

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY NOVEMBER 17 1945

THE MEDICAL FUTURE OF THE COLONIES

Although through Parliament the ordinary British citizen is responsible for the administration of the Colonial Empire it is no exaggeration to say that before this war most people were profoundly ignorant of conditions in this Empire. Private individuals were not as a rule encouraged to visit our tropical dependencies, and unless one had many personal friends in the colonies it was impossible to get a close-up view of them. During the war many people, among them doctors, have had to reside willy-nilly for considerable periods in our tropical dependencies. The degree of poverty, illiteracy, and ill-health, which cannot be hidden from even the most casual observer, has come as a shock to many who were brought up to regard the British as experts in colonial administration. It is therefore not surprising that the volume of informed criticism of the conditions under which colonial peoples live has increased, and with it a general resolve that conditions must be rapidly and radically altered. Among the tasks which must obviously be tackled on a large scale is a raising of the standard of health of indigenous populations. Peoples who from early childhood are riddled with malaria, who constantly suffer from intestinal worms, not to mention urinary bilharziasis, whose venereal disease rate is one of the highest in the world, whose diet is constantly deficient in first-class protein, even when, as in the "hungry seasons," it is not deficient in everything, whose countries are swept by devastating epidemics of cerebrospinal fever and smallpox—such peoples cannot be expected to display much energy; yet without energy they cannot hope to raise their standard of life. That the physique and mental alertness of colonial peoples can be improved out of all recognition when good food and hygienic conditions are applied has been demonstrated in no uncertain manner in the Army in the case of West and East African troops. If these things can be done in war they can likewise be done in peace. Before such an improvement can take place it is essential—yet perhaps sometimes overlooked—that there must be a highly efficient medical service. It is therefore pertinent to consider whether the medical service which now exists in our colonies is efficient, and if it is not whether it can be made so.

It is usual to speak of a colonial medical service, but it must be remembered that the Colonial Medical Service is a far more nebulous organization than that which guards the health of the three fighting Services. Its central organization consists solely of a Chief Medical Adviser to the Secretary of State for the Colonies and a small assistant staff; there are no full-time specialists or consultants such as advise, for instance, the Director-General of the Army Medical Service. Even before the war the number of colonial medical officers was quite inadequate to deal with the enormous amount of work to be done. Statements such as the following[1] were all too common: "There were in 1934 hospitals at Tamale, Salaga, Yendi, Bawku, Navrongo, Lawra, and Wa, each under the direct charge of a medical officer when one was available." At the end of the war, what with deaths, retirements, resignations, and invalidings, there is a very real possibility of a dearth of suitable medical officers for service in the Colonial Empire. In Nigeria, with a population of approximately 21,000,000—nearly half that of Great Britain—there is at present one doctor to every 175,000 people, and in certain districts one doctor for an area containing 1,000,000 inhabitants. It may be that many Service medical officers who have been stationed in the Tropics during the war will be anxious to take up appointments in the Colonial Medical Service, but nevertheless there is a widespread feeling, rightly or wrongly, that it is not an entirely happy Service. The feeling of frustration, which is far too common among medical officers serving in our tropical dependencies, is due less to the trying climate and the often inevitable isolation than to the Sisyphean task of grappling, often single-handed, with overcrowded and badly built hospitals, to inefficiency of the nursing staff, to insufficiency of up-to-date apparatus and drugs, and above all to lack of stimulus and advice from specialists in particular departments. Each colony at present has its own medical establishment with its own director of medical services. Medical and surgical specialists are available in the larger colonies, but these officers reside in the capital of the colony, and in addition to their official duties are engaged in private practice and sometimes in teaching: they do not as a rule tour their colonies or come into close or frequent contact with subordinate medical officers. The question of private practice in the Colonial Medical Service is undoubtedly a very difficult and controversial subject, and one which leads to much discontent. Of the possible reasons for joining the Service one is the hope that eventually, while still drawing a Government salary, it will be possible to carry on a considerable private practice. There are, however, comparatively few stations where large private practices are available, and hence competition for such appointments is keen. Many would welcome the abolition of private practice if it were compensated by an all-round increase in salaries derived from insurance payments by all those, native and European, who are not entitled to free medical attention.

What can be done to provide an efficient medical service for the colonies? It is suggested that to attract suitable men there should be a true Colonial Medical Service with its own Director-General, responsible directly to the Secretary of State for the Colonies. The Director-General should in his turn be advised by consultants in medicine, surgery, hygiene, pathology, and biochemical research, who though normally working at the Colonial Office would visit colonial countries at frequent intervals—a not too arduous task now that air travel has come to stay. In each colony, instead, as now, of an almost autonomous medical directorate, there should be a local director of medical services, subsidiary to the Director-General in London and again advised by consultants in the various specialties. Many more specialist appointments with additional pay should be made available in each colony, while with a more co-ordinated service it would be possible to arrange for more frequent transfer of officers from one colony to another. Thus the possibility of having one's wife and family with one would be greatly increased; the prospect of spending all one's working life on the West Coast of Africa would be small. The possibility of abolishing private practice should be considered. With a co-ordinated medical service throughout the Empire the poorer colonies would not be unduly starved of medical officers, as has happened in the past, because of the smallness of their budgets. Short-service commissions of five years with a reasonable gratuity at the end, and the provision of tropical house-physician and house-surgeon appointments in the larger colonial hospitals for a year, would do much to make up for the present shortage of staff.

---

[1] Report on the Northern Territories of the Gold Coast for the Year 1937–8, Accra.

These reforms are suggested only for European medical officers. It is obvious that if anything like an adequate number of doctors is to be provided they must in large part be derived from the indigenous population. Whether or not such medical officers are to receive their education in the United Kingdom, or in the colonial medical schools as yet hardly out of the period of gestation, it is essential that conditions in the Colonial Medical Service should be so attractive that locally trained doctors do not regard Government service as a servitude to be exchanged as rapidly as possible for the more lucrative freedom of private practice.

UNDERNUTRITION IN BELGIUM

The great advances in the science of nutrition made between the two world wars have directed attention mainly to the vitamins and to tests for vitamin deficiencies. It was commonly felt that much more would be done during the second world war both to prevent such deficiencies and to detect those that occurred. However, the diets eaten throughout Europe, in both wars, have been made up largely of wholemeal flour and vegetables. On such diets deficiency of any of the vitamins, except D, is unlikely. This is recognized in the report of the investigations carried out at the University of Liège under the direction of Prof. Lucien Brull,[1] and is confirmed by studies on the vitamin content of the blood, the excretion of vitamins, and the effect of supplements of ascorbic acid. The diets contained adequate amounts of iron. Much of this was derived from wholemeal flour, and studies described in this report indicate that this iron was well absorbed in spite of the phytic acid. Anaemia due to deficiency of iron was therefore improbable. The question then arises, What tests are there by which the effects of undernutrition of this type can be detected and recorded?

In the first place, the population as a whole lost weight. By the end of 1941 the average loss among those attending the out-patient department of the medical polyclinic at Liège was 12%. Then, with more regular distribution of rations, the growth of the black market, and increase in home-grown vegetables, weights became stabilized, and during 1943 rose to about 8% below the pre-war level. Young persons under the age of 30, however, lost only about 4.6% in weight, and recovered this loss in 1943, while those over 40 lost 15% or more and remained considerably lighter up to 1944. The more severe losses were largely of superfluous fat. Again, workers in a railway goods yard lost from 3 to 15 kg., but most of them recovered from 3 to 5 kg. in 1943. Official rations, which included almost all the important foodstuffs other than vegetables, supplied no more than 2,022 calories in March and 1,754 calories in May, 1944. The question arises, How did these workers maintain or gain weight on such scarcity rations? Actual records showed that only 5 out of 24 consumed less than 3,000 calories; some were eating more than twice the official rations of bread, potatoes, or butter, most of which must have reached them through the black market. But few exceeded the meat ration; only 5 got more than 25 g. of animal protein per day, and 11 got less than 15 g.

It has been suggested that a low intake of animal protein may lead to reduction of serum proteins. Among the out-patients seen at Liège the average concentration, calculated from the refractive index, checked by Kjeldahls, was 6.99 g. per 100 ml., and more than 7 among persons under 40 years old. This cannot be considered low. Among 100 boys and girls, most of whom were between 12 and 15 years old, the average was 6.42 in 1942; low figures were found in a group of nurses (6.54) and workers in an electric generating station (6.6). In a small group of workers the mean fell from 7.2 in May, 1941, to 6.6 in June, 1942. However, the average concentration found among blood donors in the N.W. London blood-supply area[2] in 1943 was 6.56, though the amount of animal protein in the British diet, while slightly below the peacetime level, was about double that in Belgium. Cases of famine oedema occurred, and in these the concentration of protein in the serum ranged about 4.5 g. per 100 ml.; it was shown by studies described in Prof. Brull's report that the nitrogen balance was negative on the official rations of 1941–2. But nitrogen balance became positive when enough butter was added to the diet to make the calories adequate. It appears that nitrogen balance is maintained when the calories are sufficient, unless the total protein falls to a level difficult to reach on a diet of ordinary foodstuffs; famine oedema occurs only when the total calories are low. The significance of moderate reduction of serum protein remains uncertain.

Among the Belgian children the concentration of haemoglobin was rather lower than was found in Britain in the M.R.C. survey[2]: out of 34 estimations among a group of workers, 9 only were above 14.75 g. per 100 ml., which Dumont and Dor considered to be the average level in the neighbourhood of Liège. There is therefore evidence of a slight anaemia. Low concentrations of carotene were found in the plasma of adolescents examined in April, 1942. This was probably the result of a temporary scarcity of green vegetables after a hard winter. The concentrations of vitamin A among these adolescents and among workers examined in 1941 were normal. The only other deviation from normal found was in the plasma cholesterol of the adolescents, which was 29.4% below the normal average; 11.7% reduction of lipid phosphorus could hardly be considered significant. A similar reduction of cholesterol was noted at the end of the last war.

[1] Brull, L., *Les États de Carence en Belgique pendant l'Occupation Allemande, 1940-4*, Herman et Cie, Paris, 1945.

[2] Med. Res. Cncl. Spec. Rep. Ser. No. 252, H.M. Stationery Office, 1945.

These investigations illustrate the paucity of tests for undernutrition of this type and the need for standardization of methods if conclusions are to be drawn from comparison of the results found in different places and at different times. If the serum protein in Liège were estimated by methods of the same accuracy (or inaccuracy) and under the same immediate conditions as those in the N.W. London centre, it can be concluded that the amount of animal protein in the diet is not the main factor that influences the serum protein. But Chibnall and his colleagues have pointed out that the techniques used by Kjeldahls in clinical laboratories do not estimate all the nitrogen in proteins; also, serum proteins change considerably with changes of posture and exercise. For these reasons it may not be legitimate to compare the results found in the two laboratories. It is to be hoped that every effort will be made to compare the methods used in various laboratories throughout Europe, in order that the real significance of their observations may be settled.

PROGRESS IN THE INVESTIGATION OF SHOCK

During the war a large amount of experimental work has been done, chiefly in the United States, but also in this country and in Canada, to elucidate the problem of shock. Until now little progress has been made, and shock has often seemed an insoluble problem; but recent work by Dr. Sanford Rosenthal has begun to shed new light. Many other workers have used dogs for their investigations, probably for the reason that changes in the circulation could not be readily observed in smaller animals. Rosenthal, being a pharmacologist, has learnt the lesson that it is wise to use small animals whenever possible because large groups can then be taken and the percentage in which a particular change occurs can be established. He has therefore worked on mice, and has devised methods[1,2,3] for producing burns of uniform extent, trauma of uniform severity, and, jointly with Tabor and Kabat,[4] haemorrhage of uniform degree. Rosenthal found that in all three types of injury a high percentage of animals survived an otherwise fatal injury if isotonic sodium salts were given in amounts of 10% of the body weight. This effect depended on the sodium, for all sodium salts were effective, and potassium on the other hand was deleterious. Jointly with Tabor,[5] Rosenthal has now shown that mice in which shock has been produced by application of a tourniquet are very sensitive indeed to potassium chloride, being killed by as little as one-eighth of the dose necessary to kill the same percentage of normal mice. This increased sensitiveness to potassium is specific for potassium, for, while there is some increased sensitiveness to other substances, like quinidine, it is slight. The increased sensitiveness to potassium was shown not to be due to diminished excretion in shocked mice. In another publication Tabor and Rosenthal[6] have examined the salt content of the shocked area. They "pooled" the hind-legs of groups of mice, and found that there is a fluid loss into the injured area amounting to 3% of the body weight, the sodium loss into this area being equivalent to 25% of the total sodium of the extracellular space; this area loses one-third of its potassium. In other experiments they induced shock and then studied the effect of administering NaCl by mouth: during the next two days it was mostly retained and not excreted, though in normal mice it was all excreted; the potassium excretion was much greater than in normal mice. If the potassium had not been excreted, as would have happened if the mice were suffering from anuria, the amount of potassium retained would have been toxic.

The great advantage of this new work is that it has been done on large numbers of animals, and the results are convincing. Since the increased toxicity of potassium for shocked mice has also been confirmed for rabbits, it is now beyond doubt that three important changes occur in shock: a large loss of fluid and of sodium into the shocked area and a large escape of potassium from it. The likelihood that death in shock is a potassium death is increased by this evidence. Since the urinary changes are the opposite of those in adrenal insufficiency, it is evident that this is not the cause of shock, as has been suggested.

PITUITARY STIMULATION BY LIGHT

Last year Benoit and Ott[1] summarized the results of their experiments on the stimulation of gonadotrophin secretion by light. In general, previous experiments have shown that in birds red light is most effective and blue-green light least effective. The authors made a careful study of this aspect of the subject, using immature male ducks. Variously coloured filters were placed in front of the light source and the birds were exposed for 8 to 15 hours every third day, being kept immobile at distances from the light source so arranged that the energy density of the light was the same in spite of differences in wave-length. In the intervals, and during the 3 to 6 weeks before the start of the experiment, the birds were kept in a dim blue light. Ten exposures were made and the stimulation assessed by measurement of the area of the silhouette of the testes. The curve relating increase in area to wave-length shows a gradual rise through the blue-green end of the spectrum to a peak in the red band at about 680 mμ and a rapid fall with extreme red and infra-red rays. Histologically, full spermatogenesis was present in all the birds except those exposed to blue light or infra-red rays.

When the optic nerves were cut or the eyes removed light stimulation was still effective. On the other hand the wave-length: activity curve closely resembles that of normal sight sensitivity in birds. It is concluded that light is probably effective through the retina, but is certainly effective by direct transmission, probably to the hypothalamic regions. The authors prove that the tissues of the duck's head do in fact transmit orange and red light but very little blue or green light. When, however, light is transmitted almost directly to the hypophysis through a quartz rod, blue light is very active—equally active as or more so than red light. The general shape of the curve is therefore explained by the interplay of two factors. The inactivity in the blue region of the spectrum is a measure of the insensitivity of the retina to blue light and the lack of penetration through the tissues. The increase in activity with increasing wave-length indicates the greater sensitivity of the retina and greater penetration of the tissues, reaching a maximum in the red region beyond which, though penetration may still be high, the direct effects of such long waves on the hypophysis are negligible. This differential tissue penetration in birds may not be present in mammals, since Marshall and Bowden[2] found little difference in the stimulation produced by different wave-lengths in ferrets.

The effects are probably not confined to gonadotrophin. In amphibia Voitkevitsch[3] has demonstrated an increased thyrotrophin content in the anterior hypophysis of frogs collected in spring and exposed to continuous light for 5 days. He has also shown that the effect is not cumulative, but that continued exposure to the light eventually leads to a fall towards the normal thyrotrophin content. Thus it is the increase in the amount of light that is the effective stimulus—not the absolute amount of light. This is what would be expected, as the effects described are the cause of one of the most important phases in the rhythm of Nature—the recurrence of the breeding season every spring. Ornithologists have long been aware that the young bird's fancy does not turn to thoughts of love merely because it is fine weather, but may be induced to do so in coldest winter if the bird is exposed to increasing amounts of light in the 24 hours. As the evenings begin to draw out in spring the increasing hours of light stimulate the hypophysis in birds and frogs and others, and the breeding season is with us once again.

MEDICAL RELIEF IN YUGOSLAVIA

Dr. K. Sinclair-Loutit, U.N.R.R.A.'s director for health, welfare, and displaced persons in Yugoslavia, recently gave an account at the U.N.R.R.A. headquarters in London of his experiences in that Balkan country. During an extensive tour from Belgrade through Bosnia and Herzegovina he found almost incredible destruction, with multitudes of people facing winter without shelter save for shell-holes and burnt farmhouses. An appalling condition of starvation and poverty was manifest. The unfortunate thing was that there could be no effective partial relief; it was necessary to give total relief; otherwise one might almost as well give none at all. Thus it was pointless, for example, to deposit food at certain places if no transport was available for its distribution, and for such transport as there was the truck-wear for one mile in Yugoslavia was reckoned to be equal to that for twenty miles in England. A serious outbreak of typhus occurred in an overcrowded population in Bosnia and called for unusual measures. The country was short of doctors, and it was out of the question to wait for the graduates of the next university year. Therefore the expedient was tried of training a number of high-school girls in the technique of injections, and within three to six weeks, under the supervision of a few doctors, nurses, and pharmacists, these girls inoculated half a million persons; and, thanks to the vaccine and D.D.T., the epidemic was stayed. Malaria control had to be carried out on a large scale; some villages in Macedonia, said Dr. Sinclair-Loutit, were "100% malarious." One of the legacies of Turkish occupation was endemic syphilis, and Yugoslavia was the first country in Europe in which penicillin was used on a large scale to deal with that scourge. He had been able to help the Yugoslav Government in obtaining the first supplies of penicillin for civilian use, and he gave penicillin for the first time to a case of pneumonia in a town on the border of Hungary—the man was in a moribund condition, but with penicillin rallied in a day or two. Conditions of medical practice so far as facilities and appliances were concerned were just now of the eighteenth century, while the knowledge was of the twentieth. The improvisations necessary in the medical and nursing field were extraordinary, and so were the economies that had to be practised. In Belgrade the poorest could have a physiologically adequate diet, but the deprivation of the rich milk for which Yugoslavia was famous before the war was severely felt. The Yugoslav Government in its zeal for child health had devoted one complete section of the Ministry of Social Welfare to this. A serologist from Yugoslavia was being brought to England to study methods of concentrating sera, and a British plastic surgeon was in Belgrade to establish a school of plastic surgery there.

DIETARY ACCOMMODATION IN RENAL FAILURE

The composition of the blood is determined not by what the mouth ingests but by what the kidneys hold back.[1] When critical selection is seriously reduced by disease the kidneys keep what they should excrete, and eventually there is uraemia. On an ordinary mixed diet the end-products excreted by the kidneys are predominantly acid and the protein end-products demand much renal work. In renal failure, therefore, it is reasonable to suppose that a diet which provides an alkaline ash and fewer protein end-products lessens renal work. The dietary coat can be cut according to the renal cloth, and there may then be an increased prospect of the kidneys' living within their diminished exercise tolerance. A diet conforming to these principles has been advocated by Kempner.[2] Although, perhaps, he arrives at his working hypothesis in a more original manner, Kempner reports good results in the treatment of renal disease with a diet composed of rice and fruit juices. In a daily total of 2,000 calories the diet contains only 20 g. of protein and 5 g. fat. Unless there is evidence of salt deprivation, no salt is allowed. No extra water is given, and the total fluid is usually limited to 700–1,000 c.cm. of fruit juices. A vitamin and iron supplement is given daily. Nitrogen equilibrium was maintained on the diet over prolonged periods, and there was no significant depletion of salt or fall in haemoglobin. Such a diet would be unobtainable in England at the present time, and Kempner agreed it will never be popular. The food is monotonous and does not taste good. The patient has to eat it for a long time before its full effects become apparent, and the diet becomes worthless if it is modified by so-called small or minimal additions according to the patient's own taste. There is, in fact, only one excuse for such a therapy—and that is, it helps. The most impressive effects of Kempner's diet were in chronic Bright's disease with renal failure. In more than half the cases treated there were a reduction of retained nitrogenous end-products, a fall in blood pressure, and a general clinical improvement. In essential hypertension, also, the blood pressure was often significantly reduced. The results are a reminder that even when structural and functional contraction of the kidneys is beyond repair, what the mouth ingests may rectify what the kidneys keep. It would perhaps embarrass the kidneys less in the process if they were provided with a more generous fluid intake.

The next session of the General Medical Council will begin on Tuesday, Nov. 27, at 2 p.m., when the President, Sir Herbert Lightfoot Eason, will take the chair and deliver an address.

A STUDY OF NEUROSIS AMONG REPATRIATED PRISONERS OF WAR

BY

W. H. WHILES, M.R.C.S., L.R.C.P., D.P.M.
Major, R.A.M.C.; Army Psychiatrist

The problems of the soldier returning home after a long period as a prisoner of war are so important that special study and consideration are necessary. In view of the large numbers who have recently returned and others who are yet to be repatriated from the Far East I feel that the facts already recognized should be made available. This study is based upon the investigation of 100 soldiers, all returned prisoners of war, consecutively admitted to a military neurosis hospital between January and May, 1944. As Wilson (1944) has pointed out, these patients are in many ways unlike any other type of neurotic and require special handling. This is because during their period of absence they have been living a peculiar and unnatural existence in which restrictions, boredom, deprivations, and living in a limited community are the most important features.

Clinical Picture.—All cases could be classified into the usual clinical types. Nevertheless, all patients showed certain symptoms which were more intense than is usually seen. Irritability and inability to stand any form of restriction, combined with a marked restlessness and depression, dominated the clinical picture. Paranoid features occasionally seemed striking, but these rapidly subsided as co-operation was established. The men showed limitation of all interest, difficulty in making any social contacts, poor concentration, preoccupation with their own problems, and a well-marked tendency to show resentment towards anyone and anything.

Onset of Symptoms

Pre-capture Conditions.—24% of cases had developed their symptoms before being captured. These were the usual types of psychoneurosis which show themselves under battle stress. They were mostly men with marked neurotic traits: 50% had a neurotic family history, 25% had shown previous breakdowns, and 60% had shown pronounced neurotic traits in childhood. Thus they all had a definite predisposition to break down.

On Capture and in P.O.W. Camp.—44% first showed symptoms on capture or in the P.O.W. camp. In these a wide variety of factors were of aetiological importance, but in most instances the traumatic factor was chiefly of consequence because of the way it fitted into the previous personality pattern. The last thing the men thought of before capture was the possibility of being taken prisoner; only death and wounding had been envisaged. The result was that their shock on capture was all the greater because of lack of mental preparation.

Restriction of freedom was felt by all, but the traumatic effect seems to have depended upon predisposition in the previous personality. Of particular importance was a disturbed early home life with consequent poor father relationship and a tendency to rebel. Of 30% who stressed restriction 22% had shown delinquency in childhood, such as stealing and wandering. Another 33% had had disturbed early home-life conditions, and two of these had been continually in trouble in the Army because of resentment of all discipline. Thus 55% were individuals who, from their history, one would have expected to react badly to any restriction of liberty.

Food was an all-absorbing, all-important subject in the Stalag, becoming the main centre of interest and conversation around which everything else revolved. There were, however, two main types who emphasized food problems particularly: (*a*) Men with backgrounds of insecurity who could not stand any deprivations. The limitation of food was more than they could bear; they had no faith in their ability to recuperate, and became absorbed in their fears about their bodily health with marked hypochondriacal trends. In some this was the beginning of continued dyspeptic symptoms for which no physical basis could be found. Others had shown a tendency to dyspeptic symptoms at any time of crisis in civil life. (*b*) The second group was those who had always laid particular stress on physical strength and prowess. When they found themselves becoming weak through inadequate food they began to fear that they would never be real men again.

The case of a corporal who received news that his fiancée had given him up and married someone else is of interest because it leads on to the next point—namely, guilt about being captured. He received a letter from his fiancée to say she had now got a "real" man—"not one who was a coward and had got himself captured." He commented that other men got similar letters.

The feeling of guilt at being captured was most common in the men who were of good morale before capture. Not only was this a reaction to the traditional attitude that a good soldier is not taken prisoner, but a number of men who were feeling the strain of action before capture and were having difficulty in adjustment to their fears experienced a feeling of relief when first taken prisoner. "At any rate I'm alive. The war is over for me now," were the consolations they offered themselves.

This very feeling of relief brought a subsequent feeling of guilt, and was a potent factor in precipitating the onset of depression during the P.O.W. period and of difficulties on repatriation. It made them afraid of not being wanted on return home, of being despised or thought badly of, making them withdraw into themselves, avoid company, and become suspicious of every approach made to them. It should be emphasized that in only a small proportion of cases is this sense of guilt realized by the man himself and that one must be very cautious about approaching it, otherwise acute reactions may be precipitated.

The "Release" Syndrome

The discomforts of camp life, the lack of space, the overcrowding, the lack of privacy, the outbreaks of disease, the lack of food, were all overshadowed by their resentment and disappointment at the non-fulfilment of their hopes on repatriation. Of this series 32% developed the "release" syndrome described by Newman (1944). All these showed fewer predisposing personality factors than were present in the other groups. Only 4% of them had had marked neurotic traits in childhood, 6% were cyclothymic personalities, 2% had a history of delinquency in childhood, and 2% were obsessionals but had not had previous breakdowns. These "release" problems have several aspects. The common ones of fear of open spaces and feelings of helplessness, of having to manage one's own life like a child bereft of routine and authoritarian guidance, soon faded, and were replaced by an ambivalent attitude of wanting to be free and wallow in their freedom, and a longing for the monotonous security of camp life again.

On their return to this country the men were given a long leave, and during this time they found it difficult to adjust to the changes produced here by the war. England in wartime was very different from the pre-war England of their nostalgic dreams. Some of them had little desire to mix with people, finding that they knew scarcely anything of the current topics of conversation, and wanted to shrink into themselves. Their only topic was the life of a prisoner of war, and they felt themselves in danger of becoming crushing bores on that subject. They also pictured the home standing still—home and themselves being just as they were—forgetting that with the passage of time both had changed. This is true of all men who are away from home for long; but Stalag life gives excess time for fantasy elaborations and fewer factors which bring one back to accepting reality. They could not realize other changes they would find, such as wives and relatives all working long hours. After the first rejoicing at home-coming, friends therefore seemed to have no time to give to the man returned. He felt obliged to entertain and look after himself, which is just what he cannot do at first. He feels like Rip Van Winkle—so many things are strange and different. He is shy of making a fool of himself, or making himself ridiculous asking for things in shops which are no longer obtainable, not knowing all about points and coupons. It is difficult for relatives to realize all the things which these men will find strange and bewildering. They have spent day after day in a dull ordered routine, no plans to make, no decisions to take, no responsibilities. Then suddenly they are back and have to organize their own lives all over again, often taking over responsibilities they are not yet ready for from a wife who has been carrying too much. As one man put it: "I found myself transplanted from a place of quietness to a busy town. I seemed to be trying to grasp so much all at once. I couldn't absorb it all."

One of the most important problems on return home was that of the broken marriage, which formed the main feature of 25% of the series. Relatively few of these men had known or would have tolerated the thought of their wives' infidelity while they were "in the bag," and consequently found themselves confronted with an entirely unsuspected situation. Another group of men, emotionally immature and with fundamental insecurities about their domestic situations, had found their fears of infidelity accentuated by irregular mail during captivity. This led to many misunderstandings on repatriation leave, although often there was no basis for these suspicions. Finding that wife or fiancée had become more mature, more sophisticated, or had developed new and wider interests demanded readjustments which some found impossible. In all these problems relatives may need almost as much help as the patient himself, and the psychiatrist must be prepared to encourage visits and close co-operation throughout treatment. This has been particularly stressed by Torrie (1945).

Treatment

All the usual methods of treatment—continuous narcosis, modified insulin therapy, and abreaction under pentothal—were used. Those showing acute anxiety symptoms responded best to continuous narcosis. Otherwise individual interview, augmented by group psychotherapy, was the most effective approach. By free discussion in groups they were able to ventilate grievances or misunderstandings. They discovered that others were facing similar problems, and so no longer felt isolated or "queer." Confidence rose while working out common difficulties, and they were helped to appreciate more what their relatives at home had been contending with in their absence. Social readaptation was further helped by dances and parties to which local inhabitants invited them. At first, however, most men avoided these, tending to cling to their own group and fearing to extend contacts to a wider circle. The presence of A.T.S. and V.A.D. personnel in the hospital helped to break down the barrier.

All the repatriates showed great fear of being pitied, and felt at first that no one who had not been through similar experiences could appreciate their particular feelings and problems. Consequently at interviews they needed to be allowed to lead the conversation. The normal discipline of a military hospital was relaxed and they were given more free time in which to try out the freedom which at first they found so difficult to accept. In a ward together they were able to draw a feeling of security from each other, and this could then be used to wean them from undue dependence. Gradually broadening their social field, they were later able to take part in every sphere of the full community life of the hospital.

Feeding was found to present interesting and important problems. Their lives had centred around food for so long that it had come to symbolize all their recent deprivations and insecurities. A suspicious, almost paranoid attitude about rations was sometimes apparent, and they felt they were being unfairly treated if anything different was served in any other part of the hospital. The sister in charge helped them over these and other difficulties by listening to their worries and complaints with unwearying patience.

Throughout treatment it became clear that those repatriated prisoners of war who show neurotic symptoms need a special approach to avoid their symptoms becoming aggravated into asocial trends. Careful handling and understanding not only bring a greater happiness and security to the individual but avoid what might otherwise become a wider social problem if men are left feeling restless and disgruntled because they do not understand themselves.

Summary

A review is made of 100 returned prisoners of war who showed evidence of psychoneurosis.

Factors prior to capture, in the prisoner-of-war camp, and on release are discussed.

It is suggested that the type of stress most traumatic to each individual depends upon the previous personality factors.

The importance of broken marriages and of welfare problems needing help on return home is emphasized.

The methods of treatment found most useful are outlined.

I wish to thank Col. L. M. Rowlette, D.S.O., *M.C.*, for permission to publish this paper, and Lieut.-Col. A. Torrie for his encouragement and help.

Nova et Vetera

MEDICAL POETS

Many medical men in this country have been poets—one bibliography gives 156 names—but only two, in the view of Sir **Arthur MacNalty**, who devoted his presidential address in the History Section of the Royal Society of Medicine to the influence of medical poets on English poetry, have scaled the heights of Parnassus. Those two were John Keats and Robert Bridges, and both of them abandoned medicine for poetry.

Sir Arthur MacNalty traced medical poets from the Spenserian period, beginning with Phineas Fletcher (1582–1650). The most noteworthy name among Elizabethan poet-physicians was Thomas Campion (1567–1619), who was educated at Peterhouse, Cambridge, but took no degree. His first collection of poems appeared in 1601, but not until 1606 did his name appear as a doctor of physick; he had probably studied medicine at one of the Continental universities. W. E. Henley described him as a curious metricist, and Sir Sylvanus Vivian, who edited his works, said that he was a master of subtle cadences. Sir Thomas Browne (1605–82) was not often thought of as a poet, but the *Religio Medici* was one of the most beautiful prose poems in the language, belonging to that brilliant age before poetry and prose divided their domain. A medical poet of the time of James I was Abraham Cowley (1618–67), an exponent of the metaphysical flight in poetry, whose lyrics survived in modern anthologies. Cowley never practised medicine, but, believing botany necessary to a physician, composed several books on herbs, flowers, and trees. Another medical poet of this period was Henry Vaughan (1621–95). In the neo-Augustan period there were many medical poets and wits, among them John Arbuthnot (1667–1735), friend of Pope and Swift; Sir Samuel Garth (1661–1719), Sir Richard Blackmore (1650–1729), and, in spirit if not strictly in time, Mark Akenside (1721–70), who had true poetic gifts, though his first works were overrun by learning and exactitude. Erasmus Darwin (1731–1802) must be mentioned if only for his poem *Botanic Garden*, Goldsmith (1728–74) as representing the new age in poetry when it began to deal with nature and everyday life, and Crabbe (1754–1832) as one of the last of the classicists in form and one of the first of the realists in matter.

Then came Keats (1795–1821), whose writing was the reincarnation of the Greek spirit of poetry, and whose far-reaching influence was traceable among the poets of the Victorian age. Lovell Beddoes (1803–49) had never received due recognition, perhaps because he never decided whether to devote himself exclusively to physiology or to dramatic poetry. Medicine's poet laureate was Robert Bridges (1844–1930)—her only laureate, though Southey was for a short time a medical student in the department of anatomy at Oxford. Bridges's *Testament of Beauty*, published in 1929 on his 85th birthday, was unique as the work of an octogenarian. Of his earlier poems, *On a Dead Child* could probably only have been written by one who had been a children's physician. The name of Ronald Ross should be mentioned; and Henry Head and Charles Sherrington had written poems of merit in intervals between their scientific work. But it was evident, Sir Arthur MacNalty concluded, that a divided allegiance prevented the attainment of the sublimest heights in poetry. It was fortunate that John Keats laid down his lancet to take up his lyre. The student of medicine who received the divine afflatus should decide forthwith at which altar he would serve if he desired to be pre-eminent in either calling.

THE DISCOVERY OF X RAYS

COMMEMORATIVE MEETING AT R.S.M.

To commemorate the fiftieth anniversary of Röntgen's discovery a series of meetings were arranged in London on Nov. 8, 9, and 10. An inaugural meeting at the Royal Society of Medicine was presided over by Lord Horder and attended by the Minister of Health, Mr. Aneurin Bevan, and four short addresses were given.

Lord **Horder** spoke as one who had consistently believed in the potentialities of *x* rays and had done his utmost to see that the field of medicine was infiltrated effectively by the new (as it was in his young days) method. It was actually in the year before he qualified that Röntgen announced his discovery. In 1898 Hugh Walsham wrote his first paper on the subject, saying characteristically that the experience of the last three years had been sufficient to prove the usefulness of Röntgen's discovery to the surgeon, but that in his view the systematic application of the rays to the diagnosis of chest diseases would prove of equal value to the physician. To-day there was scarcely a nook or corner of the body which had not had this method applied to it, and this was becoming more and more true in respect of function as well as of structure. Indeed, the limits of the uses of *x* rays were not yet known. The adaptation of this instrument to special purposes marched with their extended knowledge of the range and applicability of the method. The lack in the field of radiology at the present time was in respect of availability to the community.

In medicine the discovery of a principle, or of a new tool, led to an era of rapid advance, and the summation of those advances produced the corpus of knowledge which the doctor possessed at any one time. "With the discovery of principles," Lord Horder said, "we associate immortal names: Harvey, Jenner, Pasteur. With tools we associate names no less immortal: Layvenhook, Helmholtz, Laennec, Röntgen."

After those present had stood for a few moments in silence in memory of Wilhelm Conrad Röntgen, the first of the several tributes was paid by Dr. R. E. **Roberts**, representing the Faculty of Radiologists. He paid a tribute not only to Röntgen, but also to all the early workers, lay and medical, some of whom had suffered grievously in making their pioneer investigations. Radiology was indebted not only to medical men but to lay radiographers, physicists, electrical engineers, builders of *x*-ray apparatus, chemists, mineralogists, and photographic experts. What all these had contributed to the technique, the scope, and the safety of the task of the medical radiologists was beyond computation, but first of all medical radiologists recalled with admiration and respect Wilhelm Conrad Röntgen, the founder of their science.

Radiology's Position in Medicine and Surgery

Dr. **James Brailsford**, representing the Royal Society of Medicine, said that by 1896, the year following the discovery, almost every structure of the body had been investigated. In that year, during a military expedition on the Nile, fragments of metal and other foreign bodies in the tissues were detected and localized, as well as stone in the urinary tract. Fluoroscopy, stereoscopy, ciné-radiography, flash photography—in short, most of the radiographic procedures familiar to-day were devised within a few months of the discovery. The *Archives of Clinical Skiagraphy* was published in 1896, with the object of putting on record some of the most striking applications of the new photography to the needs of medicine and surgery. This was the forerunner of all the radiological journals of the world. The Röntgen Society of London was founded in 1897, preceding by eight years the foundation of the German Röntgen Society. It eventually became the British Institute of Radiology. As illustrating the advances which had been made he mentioned that a radiograph of the hand in 1896 had an exposure of 15 minutes and then only the coarse structure of the bones was revealed. With improvement in the construction of the *x*-ray tube and the speed of plates and intensifying screens, radiographs could now be taken of the thickest part of the body in one-hundredth of a second or less. Much had been learned about the normal and the abnormal; often it was possible to recognize the nature of pathological processes. In the realm of radiotherapy there had been great achievements, although the cure for cancer remained elusive.

At this point the Minister of Health had to leave, as he stated, "to meet the doctors" at the House of Commons. In reply to a vote of thanks for coming to the commemoration, proposed by Dr. Rohan Williams, Mr. **Aneurin Bevan** said that his reason for being there was to identify the Government with their grateful recollection of the work of Röntgen. He had been provided by his Department with a learned speech which he might have delivered, but to do so would have been a pretence to knowledge which he did not possess. Part of his own task was to make the discovery of healing science and art available to the great mass of the population. What better tribute could he pay as a layman to the memory of Röntgen than to try to make the results of his work available to everybody in the country no matter how poor or how remote? The desire of the Government was to create for the people the best kind of medical service that medical science could provide, and in that endeavour he knew he would have the support of all those who were working in this field.

Röntgen's Influence on Medical Physics

Prof. F. L. **Hopwood**, representing the British Institute of Radiology, said that Röntgen was a physicist, not a medical man; and it was surely no accident that it was another physicist, Silvanus Thompson, who was the prime mover in founding the Röntgen Society. Röntgen, indeed, created three new professions: those of radiologist, radio-biophysicist, and radiographer. Alluding to the great work which had been done in the field of protection and to the international agreements governing apparatus and material, he said that there need be no more *x*-ray martyrs. There was international agreement also with regard to the principles and use of *x*-ray dosage. Based on the new knowledge of nuclear physics of which Röntgen was one of the early pioneers, one line of research had led to the production of the atomic bomb, another to the understanding of the phenomena in the interior of the farthest star, and another to the production of artificially prepared radioactive elements in amounts and variety far exceeding anything previously thought possible. Prof. Hopwood mentioned the development of supervoltage equipment and the new researches in the field of radio-activity and the living cell. The "new alchemy" must exert a profound influence on the medical physics of the future. It foreshadowed a new type of therapy—radio-chemotherapy. He spoke specifically of the work of the department at St. Bartholomew's, in association with a team of workers in Berlin, the result of which had been the production of radio-activity in elements not hitherto so transformed. The new discoveries and resources of röntgenology would enable his clinical colleagues to achieve a degree of control over pain and disease hitherto unobtainable. It was in his faith that the medical physicist paid his tribute of respect and admiration for the work and gifts of Röntgen.

Mr. **Cuthbert Andrews**, representing the Society of Radiographers, paid the final tribute. In the early days of *x*-ray work, he said, the significance of the technician as distinct from the medical man had not been worked out. By 1920 some of the more far-seeing radiologists had realized that the lay worker was fast becoming a very important factor in the development of *x*-ray work. The Society of Radiographers, with the late Sir Archibald Reid as its first president, was founded in 1921. He recalled some of the well-known names, medical and lay, associated with its early days and with the development of this growing science—Robert Knox, Campbell Swinton, Harrison Orton, C. E. S. Phillips, Stanley Melville, and many others. To-day the membership of the Society was 2,123, the majority being women, and the relations between the medical radiologist and these ancillary workers were excellent.

Dr. A. E. **Barclay**, in proposing a vote of thanks to Lord Horder for presiding, recalled that Lord Horder in his Mackenzie Davidson lecture ten years ago declared himself more indebted to the radiologist than to his colleagues in other branches of medicine, not even excluding surgery and pathology. Lord **Horder** said that he still subscribed to that statement, and that certain criticisms which he had made of radiology on the same occasion were now no longer valid.

Correspondence

Acute Inversion of the Uterus

SIR,—I unfortunately overlooked the *Journal* of Sept. 15. When I read Dr. O'Sullivan's paper (Sept. 1, p. 282) I looked upon it as an interesting clinical record, but when I found from the correspondence on Sept. 15 (p. 366) that it has stimulated an advocacy to scrap the basic principle of the treatment of the complication which has proved successful for the past fifty years, or the substitution therefor of a kind of Chinese torture, I feel it incumbent to intervene.

The basic principle of the past fifty years is pointed out by Dr. Batty where he says, "Far more emphasis should be placed on the *immediate* reinversion—i.e., replacement—of the uterus *whatever* the condition of the patient," and "Surely the treatment of any case of shock is to treat the cause first if this is known." Dr. O'Sullivan suggests a method of doing this which may be an improvement on the method by manual taxis, and Dr. Batty observes, "If this simple method were used as the first treatment to combat the shock, few other measures would be required." But Dr. O'Sullivan only advocates this "before shock develops," and says the treatment is to be deferred until the shock is controlled. Again Dr. Batty gets to the core with, "But will it not usually be found that the shock appears at the same time as the inversion develops?" and he confirms Dr. O'Sullivan's observation that the degree of shock is out of all proportion to the amount of blood lost. Further, as seen from the six cases recorded, the shock is not easily or speedily combated, and, as in Dr. Batty's third case, may even cause death within a couple of hours. It is with full recognition of these facts that the basic treatment by *deep anaesthesia* and *immediate replacement* has been evolved in the past fifty years.

Munro Kerr (1916) collected 21 cases; 6 of the patients died; but he wrote: "The reduction was usually accomplished without much difficulty. In two it failed and in two it was difficult." We haven't the details of his cases, but conditions for midwifery at this time were very different from the present day; a great deal was domiciliary and conducted by very unobservant persons; therefore one is justified in assuming that there was much greater delay than in the six cases just reported, four of which occurred in modern institutions in the hands of skilled attendants. The other two patients were admitted to such an institution about two hours after collapsing.

Munro Kerr discussed the methods of treatment, essentially condemning radical surgery suggested at the time. He shows his preference for immediate replacement, while endorsing the fact that spontaneous reduction did sometimes occur, and stated, "In such cases undoubtedly deep anaesthesia and especially chloroform is of great advantage." Others with experience of the complication endorsed these views. I, from a study of the cases in the Rotunda Maternity since 1896 and my own experience of two cases, did the same. Solomons had two cases and found the treatment easy and the speedy recovery dramatic. No case of complete inversion has occurred in the Rotunda since 1915. In my book (1923) I said: "The fundus must be replaced at once. . . . Complete anaesthesia will help to relax the cervix. . . . Ergotinine and pituitrin should never be given before reduction." I saw no reason to alter the paragraph in my second book (1937).

It is worth considering the nature of the complication. There are two stages rather than types—partial and complete; they follow fairly rapidly on each other. It is not necessary for the uterus to be atonic; it may be actively contracting but going extremely flabby between contractions. The placenta may be wholly adherent *in situ*, and in that case the inversion is started by pressure from above, so-called Credé's method, or traction on the cord. More often the placenta is partially detached, and probably has some area of abnormal adhesion which drags down the fundus as the placenta is being extruded even by the uterine action, but most often aided by efforts to express it, as it is in these cases that there is some degree of third-stage haemorrhage. It is difficult to conceive how the development of the partial stage can be overlooked during the management of the third stage of labour by anyone competent to conduct even a normal case.

Two partial cases occurred in the Rotunda during my mastership, were recognized at once by abdominal palpation, the placenta was removed manually, and the mere introduction of the hand replaced the fundus. There was no shock. The reason for this is perfectly shown by Fairbairn (1924) in his illustration of a specimen of partial inversion: the fundus is down to the cervix but the ovaries are still on the brim of the inversion funnel. When the inversion becomes complete the ovaries are drawn within powerful muscle walls and subjected to severe and continued, even if intermittent, pressure. Intense shock immediately appears and persists because the cause is persisting. The condition is exactly comparable to a not uncommon sight on the football field from a blow on the testicle, or a foul blow in boxing, and the appearance of the victims very alike—pallor, sweating, agony. I think there has been a death from a foul blow in boxing, but as a rule the symptoms rapidly subside because the cause is not continuing and the footballer resumes the game. In the case of inversion the cause persists and will be removed rapidly only by replacement. If this is not effected the patient remains critically ill for several days until ovarian sensation is lost. From this it seems obvious to me that the first essential is deep anaesthesia, irrespective of the state of the patient, sufficient to eliminate all sensation, and then immediate replacement, which will be found to be remarkably easy and the manipulations for which will not precipitate further shock if the anaesthesia is complete. When the patient returns to consciousness she will be completely free from signs of shock.

Dr. O'Sullivan has suggested a remarkably interesting substitute for manual taxis, but the delay in preparing the douche may discount any advantage; to me the hydrostatic distribution appears an ideal method of applying the pressure necessary to replace the uterus, but that is all; it does not justify his and others' suggestions that the essential treatment should be deferred while shock is treated. He is also to be congratulated on his photographic enterprise, for he has produced the most perfect illustration of the condition, which I hope will take the place of the deplorable post-mortem travesty reproduced from Bumm, which is given in several old, and repeated in some new, textbooks.

To complete the subject I would like to refer to one point which was not settled definitely thirty years ago. If the placenta is partially detached, as it is in most cases, it should be removed before replacement; but if it is wholly adherent it is utterly impossible to locate the demarcation between its edge and the uterine wall, the replacement should be effected with the placenta, and when in place the edge of the placenta becomes normally evident. If this practice is adopted it will probably avoid the further complication met by Dr. O'Sullivan of a ruptured uterus.—I am, etc.,

Dublin. GIBBON FITZGIBBON.

The Aetiology of Gall-stones

SIR,—Sir James Walton (Nov. 3, p. 593) has lent the weight of his authority to the theory that gall-stones arise because of infection of the gall-bladder. In many fields of medicine and surgery there has been, since the discovery of micro-organisms, a tendency to overstress the importance of bacterial infection and to underestimate metabolic and mechanical factors. Nowhere is this more clearly seen than in gall-bladder disease. There is a considerable body of evidence, to which your distinguished contributor makes little reference, that gall-stones arise aseptically, that complicating gall-bladder lesions are essentially mechanical in origin, and that bacterial invasion is a possible but not inevitable consequence. The danger that Sir James's professional distinction may help to perpetuate a theory unsupported by scientific observation and investigation impels me to submit some of the evidence for the thesis that infection of the gall-bladder arises because of the pre-existence of stones. My argument is based upon numerous observations (only in part published owing to the intervention of the war, but see *Glasg. med. J.*, 1931; *Brit. J. Surg.*, 1934, 1937, and 1940), from which I take leave to select and quote a few.

1. Gall-stones are encountered on occasion in sterile, histologically normal gall-bladders, but inflammation or infection of the gall-bladder is excessively rare apart from the presence of stone or stones.

2. "Acute obstructive cholecystitis" is essentially a condition of infarction of the mucosa of the gall-bladder due to the impaction of a gall-stone in the neck of the gall-bladder. This is true even in the rare examples of the disease occurring in infancy.

3. While it is rare to encounter the typhoid bacillus in the gall-bladder, the biliary carrier state is dependent upon the pre-existence of cholelithiasis.

4. In a histological and bacteriological study of large numbers of surgically removed gall-bladders certain well-defined groups can readily be arranged in series as follows: (*a*) Histologically normal, sterile gall-bladders. (*b*) Cholesterosis gall-bladders, also sterile. (*c*) Histologically normal and cholesterosis gall-bladders, containing stones, but sterile. (*d*) Examples of "acute obstructive cholecystitis" (*vide supra*), from about half of which organisms are recoverable. (*e*) Chronically inflamed, fibrosed, stone-containing gall-bladders, about half of which contain cultivable organisms. (*f*) Examples of empyema of the gall-bladder, all giving positive cultures, and almost invariably containing stones.

The organisms isolated are, generally speaking, quite non-specific—e.g., coliform bacilli, streptococci, mainly non-haemolytic, occasionally anaerobic bacilli, rarely typhoid bacilli.

The conclusion seems to me inescapable that in the chain of inflammatory, degenerative, and infective processes to which the gall-bladder is subject the first incident which marks the departure from normal is the formation, as a consequence of metabolic error (in the widest sense of the term), of a gall stone or stones. The stones having formed, obstructive attacks may follow, and organisms of varying degrees of virulence find lodgment as a result of quite fortuitous combinations of circumstances.

To conclude, a striking metaphor endures when flat statements of a fact are forgotten, but in this quality of persistence danger lies, when a cherished ornamental phrase obscures truth. An excellent example of this phenomenon is Moynihan's dictum (quoted by Sir James): "Every gall-stone is the tomb-stone of a dead bacterium." It is so untrue that it has no place except on the museum shelves of surgical catchwords. If its removal seems to leave an intolerable gap I offer in its place an inelegant couplet:

> "When gall-stones dam the bilious stream
> Its banks may rot and microbes teem."

—I am, etc.,

Glasgow. W. ARTHUR MACKEY.

Acroparaesthesia

SIR,—In the *Journal* of Nov. 3 (p. 596) Dr. F. M. R. Walshe elaborates a simple explanation for the majority of cases of acroparaesthesia in women. From his array of circumstantial evidence he suggests that most cases constitute a rib-pressure syndrome due to atonic drooping of the shoulder girdle, the rib in question being the normal first rib. The word "atonic" in this sense should, I think, refer not merely to muscle, but also to ligamentous and other fibrous constituents of the shoulder girdle.

I have been more or less interested in acroparaesthesia almost since the term was first introduced fifty-three years ago (Schulze, *Dtsch. Z. Nervenheilk.*, 1892, **3**, 300), but the increased number of cases during the war (notably in hospital out-patients) made me recently sum up the main data bearing on the nature of the condition (Weber, *Med. Pr.*, 1945, **214**, 226) as I saw them, and I remarked that much still remained to be elucidated. Dr. Walshe's paper does, I think, really throw some fresh light on the subject, and he comes to a conclusion of fair plausibility. With Ben Jonson one may say:

> "How near to good is what is fair,
> Which we no sooner see,
> Than with its form and outward air
> Our senses taken be."

There is, however, one feature, which Dr. Walshe does not take into consideration—namely, the frequency of the association of acroparaesthesia in middle-aged women with Heberden's nodes. This has been obvious during the recent war, but the frequency of this association was already observed by Rosenbach (*Z. Nervenheilk.*, 1890, **13**, 199), two years before the actual term "acroparaesthesia" was first introduced. Indeed, Rosenbach, from a study of cases of acroparaesthesia, seems actually to have re-discovered and carefully re-described what we usually call Heberden's nodes. To a certain extent this association supports Dr. Walshe's explanation. In my recent account (cited above) I wrote:

> "Though Heberden's nodes may be met with in elderly women who have never done any hard work with their hands (constitutional predisposition may undoubtedly play a part), they are far more often seen in those who have had to do manual housework, more or less like a charwoman—and in those who have done much needle-work or knitting. That is why, I think, they [Heberden's nodes] have been very frequent during the recent war amongst women who previously had been unaccustomed to hard work of any kind."

Heberden's nodes, as I understand them, constitute a conservative *osteo-arthritic reaction* towards stress of work involving the finger-tips. When they commence to develop there may be slight local tenderness and redness of a mild *non-infective inflammatory* (i.e., *reactive*) nature, but afterwards, when once fully developed, they are not tender and the skin is not red over them, and they give rise to no trouble except from their unsightliness. I take it that Heberden's nodes represent a conservative reaction occurring especially in middle-aged or elderly women of an osteo-arthritic disposition as a result of too frequent (though usually mild) traumatic stress, which in many other individuals would not be sufficient to call forth any similar reaction. In other words, Heberden's nodes are the expression of a reaction towards stress of work, comparable to the stress of work which calls forth the ordinary rather mild complaint known as "acroparaesthesia." Contributory predisposing factors in both complaints probably include nutritional and general hygienic errors, climacteric changes, and over-fatigue. These considerations, as far as they go, support Dr. Walshe's main conclusions.
—I am, etc.,

London, W.1. F. PARKES WEBER.

Sciatic "Neuritis"

SIR,—Dr. J. MacD. Holmes and Mr. B. R. Sworn (Sept. 15, p. 350) have described a condition which they interpret as a primary radiculitis. In the article concerned they state: "We have not yet encountered any cases conforming to Dandy's description"—i.e., of a concealed disk.

I think the three cases they describe are examples of what Dandy refers to as concealed disks but which are perhaps better called degenerated disks (*Med. J. Austral.*, Aug. 25, 1945, p. 234). Dandy described the abnormal mobility of the vertebra above the affected disk as a method of diagnosis and location, and he made a plea for the elimination of contrast myelography in these cases. Dr. Holmes and Mr. Sworn appear to have underestimated the importance of these points in Dandy's work. No mention is made of the mobility tests in any of their operations, and in all three patients the diagnosis was made by contrast myelography. The adhesions which they describe around the nerve roots are frequently encountered with degenerate disks, and swollen oedematous nerve roots are sometimes seen. Contrast myelography is quite unnecessary in these cases, and the deliberate incision of a disk to see whether it is soft inside or not may be harmful. If a disk is normal, incision only adds to the patient's disability. The disks concerned were almost certainly abnormal, and the incision of, and insertion of a sharp spoon into, the disk would then do no harm. Considerable force is necessary to incise the posterior common ligament and insert a spoon into a normal disk (the annulus being at least 1/4 in. thick), and the soft nucleus pulposus would then escape. Mr. Sworn must be a careful and gentle dissector to demonstrate adhesions around a nerve root, and, as he does not mention that force was necessary to introduce his spoon into the disk, I feel sure that he was dealing with abnormal disks.

Dr. F. J. Clark and I failed to recognize the first two degenerated disks we encountered, and I feel sure that Dr. Holmes and Mr. Sworn have made the same error and have incorrectly interpreted the condition as a primary radiculitis. We at first failed to appreciate the importance of the pathology of the concealed disk as described by Dandy. The degenerated disk is excessively mobile, and it is recognized by its mobility. The annulus is thinned and can be penetrated by a blunt instrument without using force. Sometimes there is a hole in the annulus through which a probe can be dropped. The interior of the disk is often empty, and I have only once seen a soft brown interior.

I feel that a disk should not be incised for diagnostic purposes, as the mobility test is simple and accurate, and I would suggest that the radiculitis observed by Dr. Holmes and Mr. Sworn was secondary to a disk lesion and not a primary condition, and that Symonds's statement still holds good—i.e., "the vision of an inflamed and swollen sciatic nerve, so confidently stated to be the cause of the syndrome in question, has never yet been granted to human eyes."—I am, etc.,

Perth, Western Australia. JAMES H. YOUNG.

Nutritional Macrocytic Anaemia

SIR,—"We know now that the pathognomonic feature of this large group of deficiency diseases of the blood-forming organs pernicious anaemia and its congeners) is the proliferation of megaloblasts in the bone marrow and the restoration of the normal type of erythropoiesis by liver." It is possible, with much more justification, to be quite as positive in an opposite sense as the writer of this sentence in the leading article on the above subject (Oct. 13, p. 501), and to state that the existing evidence is against pernicious anaemia being in essence a deficiency disease; that, on the contrary, there is considerable justification for believing that its cause is organic disease of the bone marrow, and that this differentiates it from the macrocytic anaemias where only functional changes in an otherwise healthy marrow occur; that haemocytoblasts, primitive and definitive (and not megaloblasts and macroblasts), are the predominating cells in the marrow of pernicious anaemia and macrocytic anaemia, respectively; that megaloblasts and megalocytes occur only in pernicious anaemia and are quite different, in origin and morphologically, from the macroblasts and macrocytes of macrocytic anaemia; and that neither the bone marrow nor the blood in pernicious anaemia, even after prolonged treatment with liver, ever returns to normality. These and other differences between megalocytic and macrocytic anaemias are dealt with by myself in detail in the following communications: *B.M.J.*, 1930, **2**, 204, and 1942, **2**, 257 and 328; *Edinb. med. J.*, 1935, **42**, 293, and 1942, **49**, 568.

In connexion with the discussion on anaemia in pellagra, it is relevant to mention that an anaemia occurring in pigs in a condition alleged (by others) to be pellagra, and remediable in dramatic fashion by liver extract, is described by me in this *Journal* (1938, **1**, 917; 1944, **1**, 232) and in *Nature* (1939, **144**, 244).—I am, etc.,

Aberdeen. J. P. McGOWAN.

Glandular Fever with Neutropenia

SIR,—I am afraid Lieut.-Col. Gerald Slot and Major F. D. Hart (Oct. 13, p. 495) are mistaken if they think cases of glandular fever with marked neutropenia have not been published or mentioned in standard works of haematology. H. L. Tidy in his excellent survey on glandular fever (*Lancet*, 1934, **2**, 236) brings in a table of six cases from five different authors with a neutropenia of 3,000. The neutropenia may be maintained throughout the course of the disease or may change into a moderate leucocytosis and show neutropenia again in the convalescence. J. R. Paul, who described the agglutination test, found neutropenia in half of his cases (*Bull. N.Y. Acad. Med.*, 1939, **15**, 43). I. Davidson (*J. Amer. med. Ass.*, 1937, **108**, 289) mentions the case of a student with a neutropenia of 1,500 with 15% polynuclears, and of a physician who was first diagnosed as agranulocytosis. Wintrobe in his textbook of haematology (1942) emphasizes the occurrence of neutropenia, quoting seven cases of extreme neutropenia of A. Bernstein.

I may add a case of my own experience. An unmarried woman aged 21 years, seen July 16, 1939. Diagnosis: tonsillitis with moderate enlargement of cervical glands. Treatment: 3 × 1 g. sulphanilamide. July 20, 1939: condition very much worse; temperature 104°; exudate on both tonsils increased; spleen palpable. W.B.C. 2,700/2,900; differential count: mostly large lymphocytes, hardly any normal polynuclears found. Diagnosis discussed with two colleagues; ? agranulocytosis or acute lymphatic leukaemia. Large doses of pentnucleotide given. July 21, 1939: condition slightly improved. One colleague, expert on blood diseases, diagnosed from the type of lymphocytes glandular fever as probable. July 22, 1939: W.B.C. 3,600/3,800; diagnosis confirmed by Paul-Bunnell test 1/128 positive. Course of disease unusually severe, with two exacerbations with fresh exudates on tonsils, and high temperatures for nearly three weeks. The patient, who was well observed in a nursing home, showed always subnormal W.B.C.

I intended to publish this case because I thought the severe neutropenia was caused by sulphonamide therapy. But after studying the literature and in view of the small dose given I dropped the idea. In the meantime sulpha drugs have been recommended against glandular fever; though I should not go so far, I should not hesitate to give sulphanilamide in case of septic complications in spite of neutropenia.—I am, etc.,

London, W.9. F. MULLER.

Acid-fast Organisms in Gastric Juice

SIR,—Dr. John Yates rightly points out in his article (Oct. 20, p. 530) that acid-fast saprophytes may occur in the gastric juice in the absence of pulmonary tuberculosis. I cannot recall that the observation has previously been made on *resting* gastric juice, but numerous workers have reported similar findings in gastric washings; C. R. Smith (*Amer. Rev. Tuberc.*, 1944, **50**, 330) gives a fair selection of references. Some few years ago, in an article written in collaboration with the late Dr. Gregory Kayne (*Journal*, June 10, 1939, p. 1170), I wrote: "The possible confusion with acid-fast saprophytes is another strong argument against the use of the direct-smear method in connexion with the gastric contents unless animal inoculation or culture is practised in addition." Another source of error is that described by Belgorod and Schain (*Quart. Bull. Seaview Hosp.*, 1939, **4**, 182), who showed that fine particles containing tubercle bacilli (killed in sterilization) may adhere to the interior of the stomach tube or glassware and become dislodged when the apparatus is used for another patient, so giving erroneous results by the direct-smear method. For both these reasons the results of smear examinations of fluid from gastric lavage are no longer reported at this hospital.

Errors due to acid-fast saprophytes are by no means restricted to gastric-lavage examinations; such organisms have been repeatedly demonstrated in sputum, in both healthy individuals and patients with non-tuberculous pulmonary disease (e.g., S. L. Cummins and E. M. Williams, *Tubercle*, 1933-4, **15**, 49). E. R. Baldwin (*Amer. Rev. Tuberc.*, 1942, **45**, 760) found non-pathogenic acid-fast bacilli in a variety of common vegetables and fruits and commented: "The inference seems justified that acid-fast soil bacteria are so often eaten with food that cultures from the mouth or stomach contents might occasionally reveal them. The bearing this might have on diagnosis is apparent."

One or two important practical points emerge: (1) No person should be labelled tuberculous merely because a few acid-fast bacilli are identified in sputum or gastric contents (or laryngeal swab). Many bronchiectatics have been so misdiagnosed. (2) Non-pathogenic acid-fast bacilli may be present in the sputum or gastric contents of *tuberculous* patients and may cause confusion when the disease has become quiescent. In such patients also occasional dead bacilli may be extruded from an obsolescent focus. One must therefore not attach too much importance to the finding of a few acid-fast bacilli on one occasion, which are probably best ignored if they fail to grow on culture. (3) Most tuberculosis workers are agreed that the presence of living tubercle bacilli in sputum, laryngeal swab, or gastric contents must be taken to indicate active tuberculosis.—I am, etc.,

County Sanatorium,
Clare Hall, South Mimms. A. G. HOUNSLOW.

Infant Feeding and Duodenal Ulcer

SIR,—I should be interested in the experimental, clinical, or statistical basis on which Dr. J. M. Morgan's statement (Oct. 27, p. 585) is founded, that infant feeding is responsible for duodenal ulcer 25 to 30 years later. Otherwise his statement seems not justified in condemning a scientific method of infant management which has stood the test of time and proved its value, as statistics of infant mortality for the years before the 1914 war and now show. It has taught the mother punctuality and some scientific approach to the care of her infant, and, as any person experienced in the care of the infant knows, the interval between 10 p.m. and 6 a.m. is well tolerated by the infant if it is handled correctly. Small adjustments during the first few weeks may be necessary, but soon a conditioned reflex is established which allows the child the most important rest between these hours. If the child still cries in the early hours of the morning this may be due to insufficient calorie- or volume-content of the meals during the day, or even more often to the cold of the early hours. It is not yet sufficiently recognized by doctor and mothers that restlessness of the child then is often due to freezing in a damp bed with not enough blankets. A warm drink relieves this stress; of course, but upsets the routine and will lead to gastro-intestinal upset.

Duodenal ulcer may be more frequent now, but this may be only apparent because of the increased accuracy of x-ray diagnosis. If it is actually increased, why try to bring a well-established step of advance in infant management into disrepute, when other factors, as increased stress and faulty dietetic habits in later life caused by the modern conditions which followed the war, are sufficient explanation and more in line with scientific investigations? Modern youth is not allowed the comfortable ease at meals and peaceful meditating life their parents and grandparents enjoyed, and to this they themselves have added the deleterious but quite universally encouraged habit of earlier smoking of cigarettes—all factors undoubtedly promoting the formation of peptic ulcers.—I am, etc.,

K. A. GRAF.

Anaemia in the Child with Frequent Colds

SIR,—I and a number of colleagues read with some surprise and no little respect the article entitled "The Child with Frequent Colds" (Oct. 27, p. 566). One felt that respect was due to Drs. Irwin and Frankel who had the courage to draw definite and sweeping conclusions on a complaint so widespread and frequent from investigations carried out on 100 or even 130 children drawn from one small area of the British Isles. No reservations are made as to the effects of climate or of living in large industrial towns. All children are assumed to conform to those living in South-West Essex.

Another curious assertion is made farther on in the same article. It reads as follows: "Though minor degrees of anaemia occur, the children cannot be regarded as physically defective." Since 2 of the children showed haemoglobin between 60% and 70% and 6 between 71% and 80%, and since only 100 children are under consideration, then 8% of these children exhibited fairly marked anaemia. Supposing the conclusions arrived at in this survey to be accurate, then had 1,000 children been investigated, although the percentages would have remained the same, nevertheless 80 children showing the above low haemoglobin levels out of 1,000 children would surely not have passed as more or less unimportant. Of 200 cases of anaemia referred to the laboratory where I work in the past three months whose haemoglobin levels ranged between 60 and 80%, all had symptoms referable to the anaemia which cleared up when appropriate treatment was instituted. These patients were certainly not regarded by their own doctors as being without physical defect. Again, as no erythrocyte counts or blood-film examinations are discussed in the article, presumably these were not carried out. There is, therefore, no way of knowing whether the anaemias were macrocytic or microcytic or whether due to nutritional or other causes. Again, I would be glad to know the reason for the statement that "there was no relation between the positive Mantoux reaction and anaemia or frequent colds."

While I have no desire to level carping criticism at a piece of work obviously conscientiously and painstakingly carried out, I feel that such positive conclusions based on such a limited and regional survey cannot be anything but misleading.—I am, etc.,

Glasgow. ANNE C. V. GREIG.

Treatment of Denuded External Skull Table

SIR,—I was interested in the letter from Mr. G. H. Colt (Oct. 20, p. 544) regarding the treatment of avulsion of the scalp. As assistant to a plastic unit, of which Mr. Gabarro is in charge. I have had to treat seven cases of this injury in the last two years. Three admitted direct have been treated by minimal toilet, and the immediate application of a split skin-graft cut by the dermatome. The results have been very satisfactory, the first dressing after ten days revealing a complete take. In these cases the avulsed portion of scalp included the galea, and there was usually pericranium over most of the bone. Raw bone was present in two cases, however, the largest area being 3 in. in diameter, and no loss occurred over this. When seen several months after the operation the grafts were found to be movable on the skull and of very even texture.

Three other cases have been transferred to us late with a granulating surface, and grafted after preparation with "eusol" dressings. These did well, but there was not the excellent take which resulted from primary grafting. In particular, there was failure over raw bone. In 10 to 14 days after the first dressing, however, granulations spread across the areas, and complementary grafts were applied by Gabarro's method. Complete healing was achieved 7 or 8 weeks after admission, compared with 2 or 3 weeks in the cases grafted primarily. I think this again emphasizes that skin loss should be replaced as soon as possible after injury, and that in civilian type injuries, at any rate, immediate grafting is the treatment of choice.

The final case is still under treatment. Here the avulsed portion of scalp (7 in. × 5 in.) was collected from the machine and brought in sterile saline. Six hours after the injury the hair was cut away, the aponeurosis and subcutaneous tissue were removed by sharp dissection, and the resulting full-thickness "graft" sewn into position. After twelve days it was adherent but looked as if mummified. It remained like this for seven weeks, after which the outer layer began to separate, leaving what now appear to be deep skin layers, with hairs 1/4 in. long growing from it. It is hoped to report this case in detail later, but it can be said already that the very conservative line of treatment has preserved some at least of the hair follicles.—I am, etc.,

Hale, Cheshire. FRANK ROBINSON.

Rehabilitation of Fractured Limbs

SIR,—I read with great interest Sir Morton Smart's letter (Oct. 27, p. 581) describing the method of "producing controlled contractions and relaxations of any of the muscles of the body" practised by him with success since 1899. What strikes me is that either this treatment or early massage has not become standardized by the profession. There must be some explanation. On page 518 of *Manual of Surgery*, Rose and Carless (1933 edition), massage and mobilization is stressed, and the text runs: "The days of prolonged splinting and immobilization are over (or should be)."

I imagine that shortage of nurses trained in massage is responsible for the neglect of these methods, though the massage work required after weeks of immobilization must take much longer than if instituted at the start. Sir Morton Smart's electrical treatment must be much more economical of time and nurse-power, and I imagine an intelligent patient could manage the apparatus himself.—I am, etc.,

Stone, Staffs. R. MURRAY BARROW.

Subcutaneous Oxygen for Sciatica

SIR,—Mr. Herbert H. Brown (Oct. 20, p. 544) does not mention the possible danger of air embolism. When a resident under the late W. J. Adie I was taught by him to paint an iodine streak along the course of the nerve from its root origin to the ankle, and then to bring up small subcutaneous oxygen blebs at short intervals along this line; the oxygen was supposed to find its own way to the inflamed nerve. There was no rationale to this treatment other than the psychological effect.

It appeared to me that if one could get a reasonable degree of deep oxygen surgical emphysema in and around the nerve sheath one could hope to vitalize the nerve and perhaps separate some adhesions. With this object in view I used the "sparklet" pocket resuscitator holder with "J"-size oxygen bulb and nasal catheter with a No. 12 hypodermic needle (later the Sparklet company produced at my suggestion an oxygen injector with bag reservoir). I used this treatment only when all others had failed (including several patients who had been advised laminectomy) and had a large number of spectacular cures, until on one occasion (the needle apparently having slipped) my patient suddenly complained of pain over the heart and faintness; in fact he presented a complete picture of air embolism. Fortunately the infra-red lamp and nikethamide were to hand, and the patient rapidly improved and walked home half an hour later. He has never had any sciatic pain since, but neither have I used the treatment since.—I am, etc.,

Streatham, S.W.16. HARRIS AVERY.

Volvulus of the Small Intestine

SIR,—I was interested in Major R. Salisbury Woods's case of volvulus of the small intestine (Oct. 13, p. 496). I was unaware that the condition was considered as rare as he suggests. In about 15 years' experience of native surgery in East Africa I have seen at least six cases.

I have met both types: the local "knot" similar to the condition found by him, and the complete clockwise rotation of the whole small intestine on its mesentery. Symptoms of the latter may be of the "high" type with early urgent vomiting due to obstruction of the jejunum where it enters the twist a few inches below the duodeno-jejunal junction, or the obstruction may not be complete, in which case the picture is that of a lower iliac block of obscure origin with slower progress and definite distension.

In complete rotation the condition at operation is confusing, as suggested in the reference he quotes. One is presented with small intestine distended apparently throughout. The colon is empty, and there is no lump to prove an intussusception.

A clue to the problem, which has no doubt been noted before, though I have not seen it described, is that the fingers searching in the right iliac fossa for the ileo-caecal valve in order to follow back collapsed intestine to the supposed site of obstruction cannot find the caecum because it is not there. The ileum in its rotation has pulled it up and round with the valve to the limit of its mobility, and it will eventually be found tucked up deep in the right hypochondrium about "eleven o'clock."

Eventration is usually necessary. When the whole small intestine wrapped in warm saline packs is unwound anti-clockwise reduction is effected easily, and gas and fluid can be seen entering the right colon once again with the caecum back in its place.

In one of my cases a local tangle was present in addition to the complete rotation, based on a knuckle of gut adherent to an inflamed mesenteric gland. Presumably the continuance of exaggerated peristalsis had swung the whole gut round on its anchor.

I have seen the condition only in Kenya natives, who tend to overload their intestines by gorging after a period of fasting, and it must be coincidence that the European case Major Woods describes occurred also in East Africa.—I am, etc.,

Dublin. MAIBEN ROBERTS.

Descent of the Testis in Relation to Temperature

SIR,—Wing Cmdr. A. W. Badenoch's article on temperature and the descent of the testis (Nov. 3, p. 601) treats a fascinating subject that is possibly of even greater practical than academic interest—which is saying a lot. I do not see how the migration can strictly be described as "a search for a lower temperature," since it normally occurs *in utero* where the whole foetus is kept at a uniform temperature, yet it seems clear that a lower temperature than the body is essential for full spermatogenesis. Theories for the method of descent have always seemed to me unconvincing, and a case of undescended testicles I treated in 1938 seemed to suggest a more reasonable hypothesis. The boy was aged 10, no testicle was palpable on the left side, and the right one was measured as 1⅞ in. from the root of the penis on Jan. 15. On that day I gave him a first injection of 2.5 mg. of testoviron. Three days later, to my surprise, the right testicle had moved down quite half an inch and the left testicle was easily palpable. On the 21st the right testicle was only 1⅛ in. from the penis, shortly after which it got stuck in what was proved at subsequent operation to be a mass of fibrous tissue, from which it was then difficult to release it. On Jan. 25, after three injections, the left testicle was only just 1 in. from the root of the penis. It subsequently descended satisfactorily into the scrotum at a more leisurely pace, with considerable delay before actually entering the scrotum. Curiously enough it has since been liable to sudden attacks of swelling with violent pain that neither I nor the consultant he has seen have been able to explain or prevent.

The immediate question is: "What made the testicles move and how did they do so?" I had watched this lad for months beforehand, so the only explanation is coincidence or some hormone action—in this case testosterone propionate. I got a hint of the possible mode of action when we operated on the undescended testicle, for I noticed that instead of being quite compact and rounded it was rather elongated, almost like a stumpy worm, presumably owing to the epididymis being somewhat separated from the testis. Now the epididymis is liberally provided with smooth muscle, and the idea flashed into my head that the testoviron might have stimulated contractions in this muscle which had urged the whole organ forward along the fascial planes. If this is so—i.e., that the immature testicle is really a motile organ subject to hormonal control—it would at least fit in with many observations made on its normal and abnormal descent.

Turning from this academic aspect, may I suggest a few practical matters which may depend on the temperature control of the scrotum? Any youth knows the pleasurable and stimulating sensation of wearing shorts and the impact of cool air. Any physician knows that long and especially febrile illnesses such as typhoid where the scrotum is kept warm in bed may be followed by temporary or even complete impotence. Pampering and over-clothing may not diminish libido but they do virility. It is curious that the adoption of pyjamas instead of the cooler nightshirt has coincided with diminished birth rate among the pyjama population and also a tendency towards the eunuchoid or intersexual type of both men and women.

The whole subject seems worthy of serious study. It is certainly one for fascinating speculation, and Wing Cmdr. Badenoch's article, by summarizing observations by himself and others, should do much to stimulate both, for such facts as we possess suggest that male clothing—and perhaps female as well—may be having a profound biological effect on the quality of our population. Anthropologists will have much interesting evidence to adduce, but without leaving this island one can surmise that the "hardy Scots" may owe more to their kilts than some are aware.—I am, etc.,

Winsford, Cheshire. W. N. LEAK.

Medical Photography

SIR,—Having read in recent numbers of the *Journal* various letters with reference to medical photography, and as a dermatologist who has focused his attention and camera lenses on many clinical cases seen both in out-patient skin departments in hospital and in private, I would like to say that I quite agree wth Dr. Watson Smith (Oct. 20, p. 548) on the need for the photographer-physician combination; otherwise it is almost impossible to be sure that certain clinical details which one wishes to emphasize in a picture are brought out—e.g., the sheen on the surface and the angularity of a lichen planus papule, the burrow of an acarus in a scabies lesion, or the typical "apple-jelly" nodule present on diascopic examination of a patch of lupus vulgaris. I have also found out by actual experience that hospital authorities, up to the present, will not interest themselves in the matter of making provision for facilities for clinical photography. Possibly this apathetic attitude towards clinical photography might be easier to overcome in the case of the larger teaching hospitals, although it would be a great pity to neglect the vast flood of clinical medical interest that flows through provincial and other non-teaching institutions.

With regard to the statement made by Dr. Watson Smith that "no snapshot is good or near enough: a suitable camera with portrait lens is a necessity," on looking up the definition of the word "snapshot" I find it briefly described as "an instantaneous photograph taken with a hand camera." How could one take a picture, for instance, of a young baby suffering from infantile eczema of the face, who is more or less continually on the move scratching or rubbing the affected parts? All my colour photographs are taken at a speed of 1/30th of a second exposure and a lens aperture of f 3.5, while for ordinary black-and-white photographs the speed is usually either 1/40th or 1/60th second using artificial illumination. Regarding portraits or "close-ups," I think the use of a suitable extension tube inserted between the lens and the camera body is preferable to employing supplemental lenses, as the latter, apart from expense, etc., tend to slow down the rate of exposure necessary. For close-ups between 9-in. and 5-ft. distances it is essential to have some method of correcting the parallactic error associated with short distances in focusing.

Personally, for dermatological cases I much prefer colour photographs, for many obvious reasons. For demonstration purposes they have one great advantage in the fact that one gets a coloured transparency that is ready for projecting on the screen right away without the necessity for making a lantern slide from the negative. One present drawback to the coloured photograph will, I hope, very soon be removed so far as this country is concerned. It is that, evidently owing to wartime difficulties here, one cannot get colour prints or coloured enlargements made from their coloured transparencies. This has been possible now for some time in the U.S.A. by the Kodak Company, and presumably will soon also be feasible here now hostilities have ceased. As a further step in colour photography, I do not think many people have seen colour photomicrographs, but I can assure any pathologist who is interested in the matter that they are really very excellent, comparatively easy to take, require no expensive outlay, and are well worth while. I described the method of doing them in detail in the *Journal* of Jan. 29, 1944 (p. 164).

I agree with Dr. Watson Smith when he states that "in the past the pictorial art has been made too little use of in medical literature"; but even so, should we not take a lead from the most recent trend in the photographic and cinema world, where the black-and-white picture will soon be as extinct as the silent film. I possess many black-and-white and also several hundreds of coloured pictures of dermatological subjects; I much prefer the latter, and so do most medical men to whom I show them. They are a little more difficult to take and the exposure and lighting must be accurate, but then if a thing is worth doing, it is worth doing well. During the recent war years one has had to contend with very many insurmountable difficulties in colour photography, but these should soon all be things of the past.—I am, etc.,

Leicester. F. A. E. Silcock.

Study of Food Habits

Sir,—I applaud your statement of Oct. 20 (p. 536) that "it is our duty as medical men and women to see to it that the wartime improvements in the national dietary are maintained in the period of peace." It would indeed be lamentable if even such negative improvements as the enforced diminished consumption of artificial and devitalized substances, like white flour and white sugar products, were allowed to lapse.

I consider, however, that the medical profession, fully occupied as it is, and has been, with the Sisyphean task of cleaning up the mess of ill-health caused by modern living conditions, is not alone capable of instituting effective dietetic reforms, as this would involve not only the correction of faulty eating habits based on thoughtless acceptance of custom and inability to recognize or obtain health-giving natural foods, but also the overriding of vested interests which might prove an obstacle to enlightened progress.

You mention education and propaganda: excellent and very necessary, but too slow in themselves. Action must be taken now, or yet another generation will be growing up among us wearing the triple insignia of nutritional *laissez-faire*: dentures, spectacles, and appendicectomy scar. If the remedy is additional influence on nutritional legislation by doctors, aided by agricultural experts and dietitians if necessary, then let us have it as expeditiously as possible.—I am, etc.,

Hospital for Infectious Diseases, Burnley. G. Gemmill.

Nutritional Diarrhoea

Sir,—I was much interested in the leading article on nutritional diarrhoea (Aug. 25, p. 258). While serving in Burma I had the opportunity of seeing large numbers of British "other ranks" with diarrhoea which was not immediately diagnosed as either amoebic or bacillary dysentery. They were nearly all long-standing cases and corresponded with the description given by you. In a very few cases the *Amoeba histolytica* was found in the stools after much searching. Test meals and the estimation of salt in the urine were done for twenty cases. In all cases free hydrochloric acid was absent or grossly subnormal. In addition it was found that the salt concentration in 75% of cases was 3 g. per litre or less. From this it could be argued that the condition was primarily due to a shortage of salt with a resulting failure to manufacture acid in the stomach. Sodium chloride 1 drachm, with acid. hydrochlor. dil. ♏ 30, was given three times daily. This had a rapid effect. The diarrhoea diminished, the appetite returned, and the individual felt more alert. This was then boosted with nicotinic acid, multivite, and iron, according to the clinical condition. Owing to Service conditions it was not possible to see the end-result, but all made great progress before evacuation.

The underlying theory is open to argument. The suggestion to be put forward is this. In hot climates as found in Burma, with supplies difficult, it is possible that a man over a period may not take in sufficient salt to replace that lost in sweating. Sooner or later there is insufficient from which acid can be made in the stomach and the gastric acid curve fails. This results in digestion being upset and an intestinal hurry. From this follows a failure to absorb food, including vitamins, giving rise to the clinical picture. Further, I have since found that not a few men recently arrived in the East suffered from a loose stool, loss of appetite, and a feeling of mental inertia. This condition is cured most dramatically by taking salt—1 drachm three times daily. The condition is most interesting. The above argument is put forward as a possible answer.—I am, etc.,

S.E.A.C. J. C. Holman.

A Coincidence?

Sir,—Twinning has long been admitted by both the medical and the actuarial professions to be a hereditary character, and the second family described by Dr. J. C. Joyce (Oct. 20, p. 548) is a particularly good example of this. Moreover, one of a pair of monozygotic twins occasionally shows *situs inversus*. It therefore appears probable that in both the cases described the patient was one of a pair of monozygotic twins, of which the normal individual died at an early stage of gestation. It would be interesting to know, if possible, whether any of the other twins in either family show *situs inversus*.—I am, etc.,

Galton Laboratory Serum Unit, Cambridge. A. E. Mourant.

The Effects of the Rope in Rock-climbing Accidents

Sir,—As is well known, difficult rock-climbing is usually undertaken by "roped" parties consisting of two or more climbers. Where the difficulties warrant it only one climber moves at a time, and therefore on upward climbing, although not on traverses, the security afforded by the rope is complete to all except the leader. When an ascent is approaching vertical and a leader falls the force generated in the rope is very great, and, if the second man is properly placed and holding by the shoulder belay, he may be subjected to a shock load amounting to, in theory, anything from 1/2 to 1 ton, as is perhaps proved by instances of the leader's rope breaking in such circumstances.

The point arises as to the effect of this on the leader and the second, who should normally be holding the rope over his shoulder, of the result of the shock passing first to his shoulder and then to his hands which are grasping the rope. The British Mountaineering Council is anxious to secure evidence of the effects on the leader, round whose waist the rope is tied, and on the second of this great shock. In the case of the leader the shock comes on his ribs or spine. Can readers of the *Journal* give the results of actual experience of injuries sustained by the leader due to the effect of the rope on his body in the arrest of a fall? Further, can actual facts be given of injuries sustained by a second in stopping the fall of the leader, particularly where such falls have been stopped by means of the rope being held so that the shock comes primarily on the shoulders of the second.

There are probably some doctors whose work lies in Wales, the Lake District, or Scotland, where much rock-climbing is done, who could give information on these points, and records of facts would be greatly appreciated by this Council.—I am, etc.,

J. E. Q. Barford,
Hon. Secretary,
74, South Audley Street, W.1. British Mountaineering Council.

Diet in Morphine Addiction

Sir,—I feel that your correspondent Major Stungo (Oct. 20, p. 547) has not been fair to Comerford and Kirman in criticizing with such severity their paper on pellagra in a morphine addict. I fail to see why a case of pellagra should not benefit rapidly from proper diet even in a morphine addict. Major Stungo says: "In no circumstances have I ever known a patient to gain weight in the first two weeks." This statement presumably refers to morphine addicts without pellagra, but exactly how many addicts suffering from pellagra has Major Stungo treated? In my experience cases of pellagra do respond rapidly to treatment, and it appears to me credible that this case behaved in the same way. It seems to me that Comerford and Kirman have described a most interesting case, and should a similar one fall into my own hands I should not hesitate to treat it similarly. I cannot believe that the patient could obtain a supply of morphine over a period of several months while under mental hospital observation, as Major Stungo suggests, and the fact that this patient could walk several miles after discharge does not sound as if she were still taking the drug, in spite of the fact that she did not co-operate in other ways.—I am, etc.,

London, W.1. CLIFFORD ALLEN.

Telling the Patient

SIR,—The correspondence in your recent issues on "Telling the Patient" is of very real value, as this is a most important portion of our daily work and one that is only too often exceedingly badly practised. We G.P.s are infinitely better at it than the specialists because we live with and know our patients and talk their language. I know how often I have to act as interpreter of medical pronouncements. Only last week a consultant said to a patient of mine: "Well, you have no need to worry; the diverticulitis from which you suffer should respond to modern therapy, with suitable diet and antispasmodics." Outside in my car the patient said to me: "Mac, what on earth does he mean: divertic-what-you-may-call-it; and what on earth is therapy and antispas-what's-it's-name?"

The art of clear translation of medical terminology to rational common-sense phraseology which the lay patient can understand is a real and very important one, but in thirty years' experience I find it far too rare, thus leading often to confusion and even real, but avoidable, psychological trauma.—I am, etc.,

London, S.W.1. DESMOND MACMANUS.

Psychiatry in the Services

SIR,—Wing Cmdr. Bergin has raised an interesting, if ancient, problem in his letter. Briefly it amounts to the assertion that psychiatrists are frequently mistaken in the diagnoses and recommendations they make respecting Service personnel who complain of various nervous symptoms (including depression, with or without suicidal tendencies). In fact sending such a patient to a psychiatrist frequently displays merely the diagnostic incapacity of the medical officer and is the first step on the downward path for the (alleged) patient. Wing Cmdr. Bergin does not express his views quite so directly or bluntly as I have done, but endeavours to evade the more personal implication by laying the blame on the "system." Clearly, however, his meaning can only be what I have stated; a "system" doesn't diagnose or make recommendations.

While, it is true, he asks for the views of others on the subject, he must presumably be fairly sure of his own ground before he would venture to write so challenging a letter, giving instances. He has, he says, become cynical about such cases, and describes with something of an air of triumph the success he achieved with a senior N.C.O. who had become "neurotic" and whom he referred, or threatened to refer, for disciplinary action. Will he be good enough, therefore, to instruct us in his method of distinguishing between the genuine neurotic (if he believes there is such a type) and the malingerer? How did he know the N.C.O. in question was "lead-swinging"? Also, how did he know: (1) that he would recover at the threat of a court martial, and (2) that if he were court-martialled he would receive a prison sentence of hard labour? May we assume that this man is now free from symptoms? As I have said, the problem is far from being new. It has cropped up later in this war (if I may be pardoned for using the present tense; it almost appears to me justified). In the 1914–18 war Wing Cmdr. Bergin's method was the official one at the beginning. It gave place to the theory of "commotio" and later to the psychological view.

A final point needs clarification. If the psychiatrist's methods with these cases, which Wing Cmdr. Bergin condemns, result in "a chronic state of neurotic invalidism," how does he correlate this with the improvement he describes as taking place when the patients are discharged from the Service? He gives three examples of this.—I am, etc.,

London, W.1. FREDERICK DILLON.

SIR,—Wing Cmdr. Bergin has given eloquent expression to thoughts which many of us must have had during the past six years. I have always felt, however, that the first duty of the Service medical officer is to consider the efficiency of the Service which employs him, and then the individual; it goes without saying, of course, that this individual is entitled to proper medical treatment when required. Surely the uncontrolled neurotics are more nuisance than they are worth, and are better out of the Service, which they merely hinder. What to do with them in civil life is someone else's headache at the moment, though it will soon be ours as well.

At the same time Wing Cmdr. Bergin's fear that neuropsychiatry is inducing "a chronic state of neurotic invalidism" making the patients "a burden to all concerned" is hardly supported by his three instances—namely, the successful greyhound manager, the industrious waitress, and the merry gardener. Or is it? What about a later report on those three people: how long will they cope? After all, novelty is a great thing.—I am, etc.,

P. R. KEMP,
Ballykelly, N. Ireland. Squad. Ldr., R.A.F.V.R.

SIR,—Wing Cmdr. Bergin has opened a subject which has caused considerable uneasiness among a lot of Service medical officers in the last few war years. My own observations are that the Service medical officer in general and the Service neuropsychiatrist in particular have become the escape route for Service personnel from anything distasteful, be it parades, oversea service, or even life in the Service itself. Furthermore, it seems at times that there is some hidden hand guiding us towards what I consider the calamitous folly of substituting the neuropsychiatrist for the guardroom. It is alarming the number of cases medical officers get on sick parades who ask to see the nerve specialist, and one can rest assured that if granted their wish they have learnt all the correct answers to the neuropsychiatrist's questionary well in advance.

About two years ago I was in charge of a large station hospital: I found a "W.A.A.F." wandering about the main passage, obviously lost. I asked her if I could be of help and she informed me she was looking for the specialist. The conversation went something like this. *Self:* "We have a very nice selection of specialists here; which one did you want to see?" *W.A.A.F.:* "The specialist in discharges." I directed her to the gynaecologist, but, alas, my intuition was rather like Hitler's, slightly awry; she wanted to see the neuropsychiatrist.

In a train recently I sat next to two members of the A.T.S. Their conversation interested me in only one place. *1st A.T.S.:* "Did you hear about Lily?" *2nd A.T.S.:* "No." *1st A.T.S.:* "She has had a nervous breakdown and is in hospital." *2nd A.T.S.:* "Poor thing, and she's only been married a month. I expect that means she will get her ticket." *1st A.T.S.:* "Yes; it usually does, don't it?"—I am, etc.,

PHILIP H. PERKINS,
Wing Cmdr., R.A.F.

"Reasons" for Scientific Research

SIR,—My thanks to Fl. Lieut. M. Hamilton for his letter (Oct. 20, p. 549), which sent me back to the leading article on Pasteur. "Social" is the word that contains the key to the value of Pasteur's work, the answer to Fl. Lieut. Hamilton's questions, and to all our questions and plans for reconstruction. *Socius* means a companion. "Society" means a group of companions, birds of a feather. The quality of a society depends on the character of the central person round which the companions group. Its results depend on the thoroughness with which the companions put into practice the qualities of the central character. No one can say that the Belsen practitioners, though few in number, were not productive in results. Pasteur and his companions, though few in number, produced results of a diametrically opposite character to Belsen, but far greater though not spectacular, and people generally did not become companions of Pasteur. So we have less than £1,000,000 a year for medical research.

Democracy has no clearly defined character round which its adherents can rally. The common man is a character that varies in different places and at different times. So democracy, though it has innumerable adherents, cannot have companions and cannot correctly be called society. It is at best a large and ill-defined group of small ill-defined groups. Its common denominator is hard to find. Its results are great, but not in proportion to its adherents, and those results are contradictory: health and avoidable sickness; luxury and avoidable poverty and squalor; U.N.R.R.A. and the £5,000,000,000 atomic bomb.

The only society of about the same initial size as Pasteur's which can show bigger, better, and more lasting results was formed in Palestine 2,000 years ago. It suffers at present through having more colourless consenters than companions, and being more divided by ritual than united in reproducing the everyday life of its Founder. If mankind is not to destroy itself it must transfer its allegiance from the Pantheon called "democracy" to Christian theocracy."—I am, etc.,

Market Rasen, Lincs. DUDLEY F. TORRENS.

The "Stamping" of the Guards

SIR,—I have only just seen Sir Lenthal Cheatle's letter (Sept. 22, p. 404) referring to this subject. With all due respect I submit that he sees the matter in a wrong perspective. The Guards do not stamp their feet for amusement but because it is smart and impressive. In the two and a half years during which I had the honour to be R.M.O. of a battalion of the Coldstream Guards I watched them take part in ceremonial parades in many towns of Africa and Italy, and was frankly amazed at the immense and genuine rise in British prestige which invariably followed. Unfortunately Britain is lamentably bad at propaganda, but one of her few real assets in this sphere is the Brigade of Guards. I think that most medical officers in the Brigade realize this, and consider that the price—some varicose veins and a few cases of march fracture—is not unreasonable. Sir Lenthal Cheatle is quite wrong in thinking that the medical officers cannot assert their authority. The five commanding officers under whom I served invariably treated my advice with the greatest possible courtesy and consideration.—I am, etc.,

E. GREY TURNER,
Medical Directorate Headquarters, B.A.O.R Major, R.A.M.C.

Training for Released Service Doctors

SIR,—Col. C. D. Evans's letter (Oct. 27, p. 585) should arouse not only indignant sympathy but acute alarm in the minds of doctors about to be released from the Services. I was privileged to serve under him during the last two appointments of his military career. In the former he had charge of the medical services of a large area of Belgium and Holland centred on Antwerp, whose importance at the time was acknowledged by the biggest concentration of "V" bombs ever aimed at a single target. The latter post covered the district of Hamburg, greatest port on the Continent and largest city in purely British occupation. That an ex-officer who, to say the least, has deserved well of his country, and whose modest ambition is to spend a year at a bread-and-butter salary learning the specialty that interests him most, should be denied even this meagre recognition of his services on some purely technical pretext will inspire little confidence that the much-advertised Government scheme is to be taken even at its not very inspiring face value. Surely a more generous and helpful attitude to returning practitioners would do much to allay the bitterness and distrust which, all too evidently, are now undermining the unity of our profession.—I am, etc.,

G. M. ADDISON,
Westgate-on-Sea. Late Major, R.A.M.C.

Five international organizations—the International Committee of the Red Cross, the Save the Children International Union, the Caritas Catholica Internationalis, the World Council of Churches, and the World Jewish Congress—have made a joint appeal to "the countries which have food, clothing, vitamins, and medicines" to come to the resue of Europe's children before it is too late. "Only by immediate and co-ordinated effort can a colossal catastrophe be avoided," say the five organizations, which pledge themselves "to work together in meeting the needs without regard to nationality, race, or creed."

Obituary

E. E. YOUNG, M.S., F.R.C.S.

We regret to announce the death on Oct. 16 of Mr. Ernest Eric Young of Newcastle-under-Lyme, consulting surgeon to the North Staffordshire Royal Infirmary, Stoke-on-Trent, with which he was closely associated for 40 years, becoming its president in 1936.

Born in 1875, Eric Young studied medicine at St. Bartholomew's Hospital, and gained second-class honours in materia medica and pharmaceutical chemistry at the Intermediate M.B.Lond. examination of the University of London in 1899; two years later he graduated M.B. and B.S. with first-class honours in obstetric medicine, and in 1904 proceeded to the M.S. By that time he had won the Bentley Surgical Scholarship at Bart's, and served as house-surgeon there to Sir Henry Butlin, who recognized his exceptional ability, and as resident midwifery assistant. His long connexion with the North Staffs Infirmary began as resident surgical officer; he also became consulting surgeon to the North Staffs' Cripples' Aid Society, the Stoke-on-Trent Hospital, and the Leek Memorial Hospital, and surgeon to the Longton Hospital. Eric Young brought to the North Staffs Royal Infirmary an unusual organizing talent, and he established specialized services which have been of the utmost value to patients over a wide area. The high degree of professional skill he showed in his work gained him a reputation which spread rapidly through the North Staffordshire district and far beyond. He was appointed full honorary surgeon in 1927, and at the beginning of 1936 succeeded to the post of president, having before then been senior acting vice-president of the hospital and chairman of the house committee. He published a number of papers in the *Lancet* and the *Transactions of the Obstetrical Society*, and in 1937 was elected a Fellow of the Royal College of Surgeons of England without examination. He was a J.P. for Stoke-on-Trent, and held office as chairman of the North Staffs Division of the B.M.A. in 1924–5.

Sir HAROLD GILLIES writes:

Eric Young was a stalwart of the old Bart's School which comprised so many well-known and charming people. Their devotion to their profession only vied with that of Bart's. Young had that power which many of those men had in creating intense friendships —a sort of dynamic personality which prevented anyone from quarrelling with them. His interest in games and other activities in connexion with the hospital was just what one would expect from him; but one could never cease to admire the enthusiasm with which he kept right up to date with his surgery and travelled far and wide to many clinics to gain so much further proficiency. He was very fond of travelling, which came easy to him because he made such friends when he visited those various surgical clinics and conferences. The Surgical Union of Great Britain owes a very great deal to his genial and stimulating influence, and he will be sorely missed in those directions.

His life's work lay in Newcastle-under-Lyme and the Potteries, and the North Staffordshire Royal Infirmary owes its high position to Eric Young's excellent surgery and devoted interest. He held the position in that populous area of a true consulting surgeon, and one to whom all doctors and specialists in the neighbourhood could look with certain confidence. He so wished to raise the standard of surgery and lived to see this ambition well fulfilled. I feel sure that all who knew him in North Staffordshire recognize the immense services he gave to surgery. At the Royal Infirmary he was very progressive in stimulating the development of all special departments, and long before he became president of the hospital was instrumental in winning much wealth for such developments.

As a companion and as a host those who knew him were indeed privileged, but in his private life it was not only he alone but he and Mrs. Young who together constituted a centre of kindness and joy to those who were fortunate enough—and there were many—to receive their hospitality. It was a tragic but brave end with a hopeless recurrence of which he was well aware and which he hid from his devoted wife. He did a big operation within a fortnight of his death—a great surgeon and a gallant friend.

E. A. SADLER, M.D.

Ernest Alfred Sadler died at the Mansion, Ashbourne, Derbyshire, on Oct. 16. He was in his 82nd year. His strength had been failing for some time, but he had continued in his practice and had visited some patients within two days of his death.

Sadler came to Ashbourne soon after leaving Birmingham, having held resident appointments at the Queen's Hospital, where the excellence of his notes and the beauty of his handwriting became a legend. He remained in Ashbourne for more than 50 years. He was assistant M.O.H. for Ashbourne from 1894 to 1905, and M.O.H. from 1905 until he died. His major professional interest lay in a large family practice, and in this work he was not exceeded for alertness of mind, tirelessness of body, and gentleness of spirit. If one may adapt the famous description of the strawberry made by his hero, Samuel Johnson, one may write of him that "doubtless God could have made a finer country doctor, but doubtless also He never did." His professional skill remained with him to the end, and in his 81st year he did a difficult forceps delivery, and was gratified to find that his hands had not lost their dexterity. His standards of duty were truly Victorian, and even at the end of his life he would, each evening, compel his tired body to write the day's letters and reports, leaving nothing till the morrow—letters such as few persons, and perhaps no doctors, find time to write to-day—letters of counsel, of comfort, and of charm. If his ideal of duty was Victorian, his shining courtesy had an eighteenth-century air. It was formal yet benign; it was constant, for nothing surprised him out of it; it was infectious, and men grew more civilized in his company. His humanity was inspired by an unshakable belief in man's virtue, well aware though he was of human morbidity, unhappiness, and evil.

The house in which he lived and died is well remembered by all students of Boswell's *Life of Samuel Johnson*, and it has become a place of pilgrimage for Johnsonians, both English and American. No doubt its traditions in some degree formed Sadler's character and directed his interests. It was built in 1680 and rebuilt in 1765, to the design of the Adam brothers, by the Rev. Dr. John Taylor, lifelong friend of Johnson; its best features are the octagonal drawing-room and the large hall with its two beautiful alabaster columns. Sadler wrote a description of the house which was printed by his friend Dr. L. F. Powell in his great edition of the *Life* (vol. iii, p. 498). He made some other important investigations into the Ashbourne associations of Johnson, Boswell, and Taylor, to which Dr. Powell makes repeated acknowledgment in his work. In recognition of these researches Sadler was elected an honorary member of the Johnson Club of London—a distinction which brought him the greatest pleasure. He had many archaeological enthusiasms which resulted in the publication of several interesting papers, notably a fine and scholarly account of the parish church of St. Oswald, Ashbourne, published in 1934. His most important contribution to medical literature was an article in the *Birmingham Medical Review* (July, 1898, **44**, 45) on the pedigree of an Ashbourne family of haemophiliacs, an inquiry which profitably combined his medical and antiquarian interests. During his long life he had collected a good library, which was particularly strong in eighteenth-century works.

Sadler did not neglect his public responsibilities, either civic or professional. He was chairman of the Governors and Assistants of Queen Elizabeth's Grammar School (Old Trust), Ashbourne, and a former chairman of the Derbyshire Insurance Committee. The life of the country family doctor was, is, and perhaps will be, full, happy, and devoted; no country doctor has had a fuller, happier, and more devoted life than Ernest Sadler. His wife, together with two sons, one daughter, and ten grandchildren, survives him.

D. V. H.

R. D. GILLESPIE, M.D., F.R.C.P.

The following is a tribute from a Guy's colleague:

R. D. Gillespie came to Guy's Hospital as physician for psychological medicine in 1926 as a young man. He was appointed to the staff at the age of 29. His teachers, including Adolf Meyer, D. K. Henderson, and T. A. Ross, had no doubts of his future success, nor were they disappointed. His forceful personality and clear thought soon attracted to his department students of all ages. The undergraduate found at his clinics an inspiration to think for himself in terms both of physiology and of psychology, and his lectures on psychology, for which there was no signing-up or official credit, were largely attended. His appeal to the postgraduate was even greater. He gathered round him more and more of those who were attracted by his powerful intellect and critical mind. Thus despite the cares of an increasingly busy private practice, almost without effort it seemed, he built his department larger and larger. Not that there was really effortless achievement, for his work for the hospital was given without stint and at more cost to his sensitive spirit than most realized. He aimed high and found in success no solace but a stimulus to ever greater endeavour. Perhaps it was this spirit of unrest driving his great intellect which was the mainspring of his power. The facts of his personal achievement are witness to its extent. When he came to Guy's his duties involved an occasional attendance for special cases, a weekly out-patient demonstration, and set lectures, but these were soon extended to a thrice-weekly out-patient session, and out of this grew the establishment of Psychiatric Social Service and Child Guidance Clinic, and the enlistment as clinical assistants of many men who are now distinguished in psychological medicine.

His devotion to psychiatry and to his patients bore fruit, too, in another direction, for those who could bear witness to his power for individual good were ready and forward through him to help others. Thus was established the York Clinic for psychological disorders, the first institution of its kind in this country to be an integral part of an undergraduate teaching school. Built at the expense of anonymous donors, the York Clinic with Gillespie as its director came into being during the war, and has served and is serving the needs of Service and ex-Service men and women, as well as others, needing in-patient treatment. The opportunities thus afforded for teaching and research were at once and widely recognized, and in the last year postgraduate students from our own Services and those of our Allies have sought them. The enormous amount of time and energy devoted by Gillespie to the planning and development of the York Clinic in the face of great difficulties occasioned by the war was a measure of his strength of purpose and courage. At the outbreak of war he at once joined the Royal Air Force, in which for more than five years he applied himself to Service problems. Compelled to resign his commission by ill-health early this year, he returned to Guy's and continued at his work until his death.

Always somewhat aloof and inscrutable, he engaged the respect and admiration of his colleagues to a degree which forbade intimacy to all but a few, yet for them all there is a sense of grievous personal loss. "R. D." was not only the head of his department and a great name in the psychiatric world, he was a much-loved person—more loved assuredly than he ever allowed himself to know. No one appealed to him for help in vain. If it were in aid of a patient, one could rely upon his sympathy and skill: no superficial show, but all he had. If it were appraisal of an idea or theory that was sought, the reaction might be acid but was always honest and generally true. Quiet and gentle in his manner, he could flash on occasion when principle was at stake, and would never hesitate to follow the course which he believed true because it was unpopular. Serious as a rule, he had an incisive and quick wit which in conversation delighted his friends as in debate it disconcerted his opponents.

His contribution to the development of psychological medicine at Guy's Hospital can be measured to-day in the strength and size of the department he created. It will be measured in the future by the influence of his example and teaching upon many future generations of Guy's men.

Herbert Edward Durham, Sc.D., F.R.C.S., who died at Cambridge on Oct. 5, aged 79, was the son of Arthur E. Durham, sometime senior surgeon to Guy's Hospital, and a grandson of William Ellis the economist, who inaugurated secondary technical schools. He was educated at University College School, London, King's College, Cambridge, where he took his B.A. in the Natural Sciences Tripos of 1887, and at Guy's Hospital. He qualified M.B., B.Ch. in 1892, took the F.R.C.S. in 1894, and the Sc.D. at Cambridge in 1909. For a time Durham was assistant in the throat department at Guy's, and resident obstetrical officer, and later assistant M.O., at the North-Eastern Fever Hospital, Tottenham. He then devoted himself to scientific research, and held the John Lucas Walker Studentship at Cambridge, the Gull Research Studentship in pathology, and a Grocers' Research Scholarship. At the end of the last century he went out as a working member of the Tsetse Fly Disease Committee of the Royal Society. He next took charge of expeditions to investigate yellow fever in Brazil, organized by the Liverpool School of Tropical Medicine, and beriberi, organized by the London School of Tropical Medicine. Owing to impaired vision he had to give up active prosecution of research and worked for 30 years as supervisor of the laboratories of H. P. Bulmer & Co., Ltd., cider-makers, at Hereford. He published many papers on medical, pathological, and hygienic subjects, and on horticulture and fruit-growing.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

Refresher Courses for Medical Officers released from H.M. Forces

A 14-day general refresher course will begin on Monday, Dec. 3, at Southend-on-Sea General Hospital, and a special 14-day course on "Pulmonary Tuberculosis, its Differential Diagnosis and Treatment," at Addenbrooke's Hospital, Cambridge, in conjunction with Papworth, on Jan. 14, 1946. General practitioners may attend these courses should vacancies occur. No accommodation is provided, and all those attending must make their own arrangements. Applications for further information and admission should be made to Dr. Firth, Trinity Hall, Cambridge.

The Raymond Horton-Smith Prize for 1944–5 is awarded to R. I. N. Greaves, M.D., for his thesis on the preservation of proteins by drying, with special reference to the production of dried human serum and plasma for transfusion. G. W. Harris, M.D., is *proxime accessit* for his thesis on the secreto-motor innervation and actions of the neuro-hypophysis, an investigation using the method of remote control stimulation.

During October the titles of the degrees of M.B., B.Chir. were conferred by diploma on M. M. Mason, of Newnham College.

UNIVERSITY OF SHEFFIELD

At a meeting of the University Council, held on Nov. 2, the following appointments were made: *Lecturer in Medicine,* Dr. T. E. Gumpert, F.R.C.P. *Lecturer in Surgery* and *Lecturer in Surgery to Dental Students,* Mr. J. C. Anderson, F.R.C.S. *Lecturer in Industrial Medicine,* Dr. G. B. Oliver. *Tutor in Surgery,* Mr. A. G. Butters, F.R.C.S.

Profs. H. N. Green, M.D., and Wilson Smith, M.D., were appointed representatives of the University on the Sheffield Hospitals Council.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW

At the annual meeting Mr. William Alexander Sewell was elected President; Dr. Geoffrey B. Fleming, Visitor; Mr. Walter W. Galbraith, Honorary Treasurer; Dr. W. R. Snodgrass, Honorary Librarian; and Mr. Andrew Allison, Representative of the Faculty on the General Medical Council. The following were elected members of the Council: Dr. John Gardner, Mr. Archibald B. Kerr, Mr. G. T. Mowat, Mr. James H. MacDonald, Mr. J. W. Macfarlane, Mr. Eric G. Oastler, Mr. Charles Read, Mr. Matthew White, Dr. J. H. Wright, Mr. Roy F. Young.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND

At the monthly meeting of the President and Fellows of the College, held on Nov. 2, Dr. Maurice Gerald Nelson and Dr. Michael Stanislaus O'Beirne were admitted Licentiates and Members of the College.

Medical Notes in Parliament

The Government and the Hospitals

Mr. Churchill on Nov. 8 asked Mr. Attlee by private notice whether in view of the public anxiety aroused he would state the decision reached by the Government on the future of hospitals, both voluntary and municipal.

Mr. Attlee replied that the Government could not be held responsible for any anxieties caused by unauthorized statements in the Press. The Government was not in a position to make any statement on the matter at present.

Mr. Churchill asked the Prime Minister to take into consideration that considerable harm had been done by an unauthorized statement, and that the springs of private charity might dry up before public benevolence began to flow. He pointed out that from day to day people were giving large sums to the voluntary hospitals or were leaving sums under bequests and that great disturbance had been caused by this unauthorized publication. Mr. Attlee said he was not prepared to admit that there had been a leakage of the Government's intention. He had made inquiries and could not find that there had been any leakage. He hoped that in view of his statement the general public would not be deterred. Mr. Churchill asked whether the House could now take it that these were idle and unauthorized rumours and that when the Government had a plan it would announce it. Mr. Attlee replied that at the right time a statement would be made by the Government. The intention was that it should be made to the House of Commons. The Government could not be responsible for intelligent or unintelligent anticipations or imaginations in any section of the Press.

Penicillin Supplies

New factories for production of penicillin are under construction, which, with those now working, will provide sufficient to meet all foreseeable requirements. The Ministry of Supply is consulting with Mr. Bevan with a view to penicillin, "as soon as supplies permit, being made more widely available for use by doctors in those cases where experience indicates the need for its use."

Publicity for Diphtheria Immunization

The expenditure on publicity for the immunization of children against diphtheria has been: 1940–1, £800; 1941–2, £2,276; 1942–3, £19,909; 1943–4, £30,777; 1944–5, £32,467. Since the immunization campaign started the number of deaths from diphtheria has fallen to one-third of the pre-war average. The number of cases has fallen by 28,000. Mr. Bevan calculates this means a saving of £800,000 for hospital care.

Doctors' Cars

Mr. John Foster suggested on Nov. 5 the granting of permits for reconditioned motor cars to doctors demobilized from the Services. Mr. Alfred Barnes said the present limited supply of these vehicles fell far short of the number of deserving applications from disabled ex-Service men, nurses, and midwives, for whom they were being reserved. He regretted that he could not adopt Mr. Foster's suggestion.

Mr. Dalton refused on Nov. 6 to arrange for qualified medical practitioners to be allowed to buy motor cars free of Purchase Tax for use in their professional duties. He said that administratively the remission would be very difficult.

Demobilization of Doctors

Mr. Key said on Nov. 6 that the demobilization of doctors was receiving the urgent consideration of the Ministers concerned, and a statement would be made as soon as possible.

Sale of Practices

Mr. Bevan told Sir Ernest Graham-Little on Nov. 7 that he was aware that the uncertainty as to his future intentions with regard to the continuance of the system of sale of practices was causing difficulties for doctors who were being demobilized in making agreements necessary to settle in practice. Asked to announce his policy, Mr. Bevan referred to an answer he had given on Oct. 11.

Shortage of Nurses

In a statement on Nov. 8 Mr. Bevan said Mr. J. Westwood, Mr. G. Isaacs, and he had considered what action could be taken to remedy the shortage of nurses and domestic staffs in hospitals. They had consulted with representatives of hospital authorities and the organizations and trade unions representing nurses, midwives, and domestic staff. An agreed statement would be issued on Nov. 10. This dealt with the extent of the need and the causes of shortage and outlined the administrative measures which would be taken in an endeavour to remedy the present unsatisfactory position. He added that an urgent appeal was made in the statement to men and women to offer their services in one or other of the many fields of hospital work. This appeal would be supported by appropriate publicity. Publicity was not in itself sufficient. Conditions of service were of equal or greater importance, and codes had been drawn up in agreement with all concerned defining the conditions which it would be the aim of the Government and hospital authorities to ensure. The Government recognized many long-term problems relating, for example, to the training of nurses and the prevention of wastage. These could not be dealt with fully in the statement and would require continuous study. The Government would give close attention to these matters.

Civilian Doctors this Winter

Mr. Bevan told Cmdr. Douglas Marshall on Nov. 8 that in the United Kingdom the present proportion of civilian doctors of all kinds to population was about 1 to 1,350, or in the case of general practitioners only, 1 to 2,500. The extent to which this position would be improved during the winter depended on the number of doctors to be released from the Forces, which was receiving the urgent consideration of Ministers. Mr. Bevan added that the shortage of civilian doctors was itself an obstacle to organizing in advance any mobile units, although if the need arose mutual assistance would be arranged locally. He said he had arranged with Service Ministers for the loan of medical officers so far as their resources permitted if an urgent need arose.

Diphtheria Immunization

A statement circulated by Mr. Bevan on Nov. 8 shows that the numbers of children under 15 immunized against diphtheria in England and Wales under local authority arrangements during the past five years were:

1940 and 1941 (separate totals not available)	2,365,400
1942	1,399,750
1943	1,039,490
1944	561,320

In the same period, during which diphtheria mortality in this country fell by nearly two-thirds, of 135,431 children notified as suffering from diphtheria 17,084 were immunized; and of 3,346 children who died from diphtheria 118 were immunized and 3,228 unimmunized. He added that the cost of carrying out immunization fell on local authorities except for the cost of the toxoid supplied to them free by the Government, which has averaged about £13,500 a year. He had no information about the number of doctors who, as medical officers of local authorities or as practitioners engaged on a sessional basis, had taken part in this work.

The Public and the Common Cold

Cmdr. **Maitland** asked Mr. Bevan on Nov. 8, in view of the number of working days lost during the winter months by epidemics of the common cold and influenza, to initiate a nation-wide campaign to encourage the voluntary use of inoculation against these diseases and to arrange for the inoculation to be given at the expense of the Government. Mr. **Bevan** said the general results so far obtained of inoculation against the common cold and against influenza were not such as to justify the measures suggested. The publicity campaign would be actively continued, to make known the rules of healthy living and to check infection through careless coughing and sneezing.

The Invalided Psychoneurotic

On Nov. 8 Sir **Ian Fraser** asked the Minister of Pensions to undertake an inquiry into the attitude of his Ministry towards cases of psychoneurosis with a view to securing more sympathetic and generous treatment of them.

Mr. **Paling** said he was satisfied that cases of psychoneurosis were sympathetically and generously treated by his Department. As in the case of any other disability, pension was dependent on whether the condition was causally connected with war service. But where a man who had been invalided for psychoneurosis was in need of and likely to benefit by institutional treatment, free treatment was provided in special centres even though the condition was neither attributable to nor aggravated by war service. Attention was given as part of the treatment to the man's re-establishment in employment, and where necessary vocational training was arranged.

Raynaud's Disease and Vibrating Machines

Dr. **Morgan** inquired on Nov. 8 whether any reports had yet been made of the number of cases with an increasing incidence of alleged Raynaud's disease or dead hand or disabilities classified as vibrational diseases as the result of handling by workmen of vibrating rotating machines in a factory at Trafford Park, Manchester.

Mr. **James Griffiths** answered that he had no information in regard to such cases at a factory at Trafford Park. Extensive investigations had been carried out by the Medical Inspector of Factories and the Medical Research Council in collaboration into the effect of electrically driven vibrating tools in factories in Lancashire and Cheshire. These had not disclosed evidence of disability beyond frequently recurring transient effects, which in some cases might be sufficient to cause the man to seek a change of employment. There was not enough evidence that Raynaud's disease was so specific to employment as to justify its inclusion in the Schedule of Industrial Diseases under the Workmen's Compensation Act.

Public Assistance Medical Care.—Mrs. **Castle** suggested on Oct. 25 that the Minister of Health should, pending the establishment of a national health service, encourage public assistance authorities to introduce the open-choice system of medical assistance for needy persons not covered by the Health Insurance Acts, so that they could obtain free medical treatment from their own doctor. Mr. **Bevan** said he was prepared to consider favourably any application for his consent from a public assistance authority which found it practicable to introduce the open-choice system.

Medical Examination of Tin-miners.—Mr. **Beechman** on Oct. 25 asked the Minister of National Insurance to ensure that intending tin-miners were medically examined before they took up work and that all tin-miners had periodical medical examinations. Mr. **James Griffiths** regretted that the difficulty of finding doctors with the special experience necessary to carry out the examinations made it impossible now to propose such extension of the statutory requirement. The matter would be kept under review.

The Services

The following have been awarded the R.N.V.R. Officers' Decoration: Surg. Cmdr. H. P. Widdup, Acting Surg. Cmdr. D. A. Imrie, and Surg. Lieut.-Cmdrs. P. D. Daly, M. G. Stratford, W. G. Campbell, and W. Gough, R.N.V.R.

The following awards and mention in dispatches have been announced in recognition of gallant and distinguished services in the field:

M.C.—Major (Temp.) O. G. Prosser, Capts. E. F. M. Caraher and A. C. P. D. Thomson, and Lieut. M. A. Egan, R.A.M.C.

Mentioned in Dispatches.—Capt. D. R. Macaulay, R.A.M.C.

Repatriated.—Capt. Hugh Edward De Wardener, R.A.M.C.

CASUALTIES IN THE MEDICAL SERVICES

Killed.—Surg. Lieut. Colm Nolan, R.N.V.R.

Killed in road accident in Rome.—Major John French, R.A.M.C.

Wounded.—Surg. Lieut. J. Wedgwood, R.N.V.R.

Medical News

A sessional meeting of the Royal Sanitary Institute will be held at Halifax Town Hall on Saturday, Nov. 17, at 10.15 a.m., when papers will be read by Mr. J. W. Beaumont on "Rodent Control" and by Dr. G. C. F. Roe on "The Nature, Incidence, and Treatment of Mental Defect."

A course for Dominion and Allied Forces arranged by the British Council at the Overseas Club, Birmingham, from Nov. 19 to 24, will include a talk by Dr. H. Guy Dain, Chairman of Council of the B.M.A., on "The State and Medicine."

Dr. A. S. Parkes, F.R.S., will speak on "Some Problems of Reproductive Physiology" at a meeting of the Eugenics Society to be held on Tuesday, Nov. 20, at 5.30 p.m. in the rooms of the Royal Society, Burlington House, W., with Mr. Eardley Holland, P.R.C.O.G., in the chair. All interested in this subject are invited to attend.

Dr. G. Macdonald, Director of the Ross Institute, London School of Hygiene and Tropical Medicine, will read a paper on "Tropical Hygiene and the Oversea Empire" at the Royal Society of Arts, John Adam Street, Adelphi, on Tuesday, Nov. 20, at 1.45. Sir Rickard Christophers will preside. Tickets may be obtained from the acting secretary of the Dominions and Colonies Section, Royal Society of Arts, John Adam Street, London, W.C.2.

A meeting of the Medico-Legal Society will be held at 26, Portland Place, W., on Thursday, Nov. 22, at 8.15 p.m., when a paper will be read by Mr. T. Mervyn Jones on "The Medico-Legal Aspects of War Injuries."

A general meeting of the Medical Society for the Study of Venereal Diseases will be held at 11, Chandos Street, W., on Saturday, Nov. 24, at 2.30 p.m., when an address on the prevention of syringe-transmitted hepatitis will be given by Major S. M. Laird, R.A.M.C.

The British Empire Leprosy Relief Association has arranged a public meeting to be held at Friends House, Euston Road, N.W., on Tuesday, Nov. 27, at 6.30 p.m. The Archbishop of Canterbury will take the chair and Dr. Ernest Muir is among the speakers. An exhibition will open at 6 o'clock; there will be a cinematograph film, and singing by the Toc H male voice choir. Admission is by ticket (free) on application to the Organizing Secretary, B.E.L.R.A., 167, Victoria Street, S.W.1.

An open meeting of the Neurosis Subcommittee of the Royal Medico-Psychological Association, to which all interested are invited, will be held at 11, Chandos Street, London, W., on Thursday, Nov. 29, at 11 a.m., when there will be a discussion on "Education in Mental Hygiene," to be opened with short papers by Dr. Clifford Scott and Dr. R. Sutherland. The next quarterly meeting of the Association will be held at 11, Chandos Street, W., on Friday, Nov. 30, at 10 a.m., when papers will be read by Dr. Elizabeth Casson on "The Psychiatric Approach to Work of Rehabilitation" and by Dr. T. M. Ling on "Psychiatric and Industrial Aspects of Rehabilitation." A discussion will follow. At 2.30 p.m. the twentieth Maudsley Lecture will be delivered by Sir Laurence Brock, lately Chairman of the Board of Control, on "The Place of Psychiatry in the Public Health Service," at the Royal Society of Medicine (1, Wimpole Street, W.). Psychiatrists and other medical practitioners, psychologists, and members of the legal profession, teachers and students, and all interested are cordially invited to attend. Admission is without ticket.

Members of the Welsh Branch of the Society of Medical Officers of Health from a wide area, accompanied by their wives, attended a complimentary dinner in honour of Prof. Ralph M. F. Picken, Acting Provost of the Welsh National School of Medicine, and immediate past-president of the Society of Medical Officers of Health, at the Park Hotel, Cardiff, on Nov. 8. Prof. Picken was accompanied by Mrs. Picken, and the toast of the evening was proposed by Dr. D. Rocyn Jones, Medical Officer of Health for Monmouthshire, seconded by Dr. E. Colston Williams, late County Medical Officer for Glamorganshire. Dr. James C. Gilchrist, Cardiff (president of the Branch), presided.

On Oct. 20 (p. 543) Sir Arnold Lawson, president of the Royal Medical Benevolent Fund, made a moving appeal for contributions to the Christmas Gifts Fund. Readers who meant to respond but have not yet done so are asked to send their contributions marked "Christmas Gifts" to the Secretary, R.M.B.F., 1, Balliol House, Manor Fields, Putney, S.W.15.

The fourth All India Obstetric and Gynaecological Congress will be held in Lahore in December. The subjects for discussion are: puerperal sepsis, pelvic inflammation, and ante-natal care. The address of the Secretary of the Scientific Section of the Reception Committee is 39, Chamberlain Road, Lahore.

The faculty of the Medical School of the University of Rio de Janeiro has recently conferred the degree of doctor *honoris causa* on Dr. Pasteur Vallery-Radot, head of the French Cultural Mission to South America now at Rio de Janeiro.

The Board of Control wishes to remind medical practitioners who before enlistment had been approved for the purpose of making recommendations in respect of voluntary and temporary patients under the Mental Treatment Act, 1930, and who are returning to civilian practice from the Forces, that before making medical recommendations under the Act they should ascertain by inquiry addressed to the Board of Control at the Clifton Hotel, St. Annes-on-Sea, Lancashire, whether their approval is still current. This is necessary as in some cases approvals may have expired during the absence on service of an approved doctor.

Dr. William Baron Cockill, who has long practised at Kendal and is a J.P. for Westmorland and consulting physician to the County Hospital, has been made an honorary freeman of the borough of Kendal.

Prof. L. P. Garrod has lately visited Belgium to lecture on penicillin to medical audiences at the invitation of the University of Louvain and under the auspices of the British Council.

Dr. Alizon Frances Stookes has been released from internment in Japanese hands.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* infectious diseases were slightly less prevalent than in the preceding week, the only exception being acute pneumonia, notifications of which went up by 29; the incidence has increased by 81% during the past four weeks.

The largest variations in the incidence of diphtheria were a rise of 13 in Durham, and a fall of 20 in Lancashire. London reported 32 fewer cases of whooping-cough than last week. The largest new outbreak of this disease during the week was in Merioneth, Dolgelley R.D., 18 cases.

No fresh outbreak of dysentery was reported during the week, and the total notifications fell by 37. The largest returns were Lancashire 67, London 43, Warwickshire 21, Yorks West Riding 13, Glamorganshire 13, Middlesex 11, Essex 10.

For the six weeks ended Oct. 20, influenza deaths in London and 126 great towns numbered 54 as compared with 96, 75, and 60 in the corresponding period of the last three years.

In *Scotland* there were increases of 24 in the incidence of diphtheria, and of 31 for whooping-cough, while notifications of scarlet fever fell by 22, and of dysentery by 21. The only large return of dysentery during the week was that of Glasgow, where 35 of 66 cases were notified.

In *Eire* there was a general fall in the incidence of infectious diseases, notifications being fewer than last week by the following amounts: diphtheria 16, enteritis and diarrhoea 16, measles 46, scarlet fever 15, whooping-cough 21. Fifty-one of the 65 cases of diarrhoea and enteritis were reported from Dublin C.B.

In *Northern Ireland* notifications of diphtheria rose by 11, and of scarlet fever by 12.

Week Ending November 3

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,819, whooping-cough 1,041, diphtheria 585, measles 496, acute pneumonia 458, cerebrospinal fever 35, dysentery 211, smallpox 1, paratyphoid 6, typhoid 9, poliomyelitis 24.

No. 43

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Oct. 27.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1945					1944 (Corresponding Week)

ANY QUESTIONS?

Exercises during Pregnancy

Q.—*What is the value of exercises in pregnancy, with the idea of freeing the pelvic joints for labour?*

A.—There are many exercises designed to loosen pelvic joints, and the following are examples:

1. Swinging first one leg and then the other while holding on to a support. Forward and backward kicking and circular movement of the leg.
2. Standing in front of a chair and raising each foot in turn and placing it on the seat.
3. Flexion and extension of the trunk, bending low as if to "touch the toes."
4. Squatting low with the knees well apart, and also with knees together.
5. Ascending and descending stairs, two at a time, without the support of the banister.
6. Kneeling and alternatively adopting the knee-chest position and sitting back on to the heels.

Exercises of such kinds are advised for the later weeks of pregnancy, but can with advantage be performed regularly throughout pregnancy. Those who believe that free movement of the pelvic joints is important for natural delivery emphasize the need for such movements—e.g., manual labour involving low bending, and low squatting for defaecation during earlier life. Reference should be made to *Safe Childbirth* by Kathleen O. Vaughan (Baillière, Tindall and Cox, London, 1937). Antenatal exercises are also mentioned in several of the semi-scientific books written for expectant mothers; yet they receive scanty if any mention in obstetrical textbooks. This is probably because most obstetricians appear to take the view that set exercises are rendered unnecessary if a woman performs her normal household duties, which involve bending, stooping, kneeling, scrubbing floors, running up and down stairs, etc.

Cholecystitis: Diet and Treatment

Q.—*With reference to the question and answer "Heartburn and Cholecystitis" in the* JOURNAL *of Sept. 22 (p. 412), I would be grateful for detailed instructions on the treatment of this condition, with special reference to diet and medicinal treatment.*

A.—On theoretical grounds which are difficult to defend, various diets have been prescribed for cholecystitis. In particular, a low-fat diet has been recommended because the liver may be diseased, or because the flow of bile is scanty, or because cholesterol forms gallstones. In the ordinary uncomplicated case of cholecystitis there is no reason to believe that any of these fears is justified. Fat is the normal stimulus for the discharge of bile into the duodenum, and this promotes the drainage of the biliary system. The dyspepsia of cholecystitis is probably due to reflex disturbances of gastric tonus, and the diet should be planned from this point of view. Provided fried foods and indigestible types of fatty foods, such as pork, are avoided, the patient should tolerate ordinary quantities of natural fats, such as butter, milk, cream, and eggs. Small dry meals are probably better than slops, as in other forms of gastric flatulence, and fluids should be taken between meals. A bland diet should, therefore, be planned on these lines. Spices and condiments, rich foods, new bread, hot rolls, pastry, and gaseous vegetables such as turnips and those of the cabbage family, should be avoided, and raw fruit and greens taken with forbearance. Many patients with cholecystitis are obese, and their diet should be reduced to a level at which they will lose weight.

Biliary antiseptics are probably of little value. There is no evidence that hexamine or sodium salicylate is excreted in the bile in antiseptic concentrations. Sulphonamides, on the other hand, do reach effective levels in the bile, but they are dangerous drugs to give over long periods of time. Medicinal treatment therefore comes down to biliary drainage and symptomatic remedies for dyspepsia. Biliary drainage is best promoted by a teaspoonful or more of 25% solution of magnesium sulphate on waking in the morning, and a dessertspoonful of olive oil before the midday and evening meals. For the flatulence alkalis may be given combined with carminatives such as cardamoms or spirits of ether.

"He Died Peacefully . . ."

Q.—*The Press frequently report, "So-and-so died peacefully in his sleep." Excluding senile decay or a ruptured brain vessel, is there any justification for such statements? Novel writers also dispose of characters by the same procedure. One must also exclude "coma" from various causes. What proportion of people "die peacefully"?*

A.—It is impossible to say what proportion of people die peacefully during sleep, for there are no available statistics. If senile decay, cerebral haemorrhage, and coma from various causes are excluded, as the question suggests, the number is probably fairly limited.

A distinction must be drawn between those suffering from an advanced disease and those apparently healthy. In the former, death frequently occurs in the early hours of the morning during sleep and occasions no surprise. On the other hand, death of this sort is quite unlikely in the latter group, but it may arise in people with unsuspected disease of the heart, such as coronary disease or fatty degeneration. In young children, sudden death sometimes happens from bronchopneumonia and gastro-enteritis which had given rise to no serious symptoms. Such death may take place during sleep.

Disseminated Sclerosis and Trauma

Q.—*A patient suffering from severe injury to the left leg followed by osteomyelitis necessitating amputation develops disseminated sclerosis. Could the shock of the injury or the sepsis be a causative agent? History: injury December, 1940; sepsis—osteomyelitis; amputation December, 1942; symptoms of disseminated sclerosis first noticed November–December, 1942.*

A.—Many cases similar to this have been reported, and some clinicians find it difficult to resist the view that severe trauma may cause disseminated sclerosis to develop. Isolated cases, however, prove nothing statistically, and one has to set against them the enormous number of injuries which are sustained by young men in wartime and which are not followed by disseminated sclerosis. Since we do not know the cause of the disease we can neither explain how an injury could precipitate it nor on *a priori* grounds exclude the possibility. In the present state of our knowledge, therefore, the only possible proof is a statistical one, in the absence of which the verdict must be "not proven".

Methods of Vaccination

Q.—*I would be grateful for an opinion on the intradermal method of vaccination. In my experience this method never causes a patient the slightest inconvenience. Difficulty in following up cases has prevented a personal opinion on its efficacy. Many practitioners, both recently qualified and with long experience, still seem to use the "scratch" method.*

A.—The objections to injecting vaccine lymph intradermally are that it contains glycerin, which is an irritant, and may, in spite of glycerination, contain living bacteria, which are much more likely to cause secondary infection if actually injected into tissue. The scarification or multiple-pressure methods (see *B.M.J.*, 1944, 2, 781), in which the lymph is placed on the surface and the vaccinia virus is simply given access to epidermal cells by very superficial trauma, have not these objections; they are fully efficient and simpler to perform.

"Difficult Eaters"

Q.—*Not uncommonly mothers come to me with the complaint that "I can't get my child to eat." Physical examination usually excludes such possible causes of anorexia as tuberculosis and rheumatism. I would like advice on the general management of the "difficult eater." Would there be any point in prescribing vitamin B_1 in such cases, even though one knows the daily menu is satisfactory?*

A.—This common problem is most difficult to solve without much more information, and preferably with an interview so as to see exactly the mother-child relationship. It is not the type of question to be answered by correspondence. Moreover, the question raises difficult points, for neither tuberculosis nor rheumatism is at all likely to produce anorexia as a *dominant* symptom in a child, nor are they easy to exclude by physical examination. The sort of approach may be on the following lines: Is there any intestinal trouble? State of teeth and throat? Is there chronic infection of tonsils, lungs, kidneys? What is the daily dietetic programme? Is the child allowed to get hungry by a strict three meals a day, or is milk, apple, orange-juice, or cod-liver oil, for example, allowed to spoil the development of an appetite? Does the child feed alone?

Is there active resistance or a mere passive lack of interest? Is there anything the child really likes? What is the age? Does he go to school? Is he any better eating with strangers or in company? Mere prescribing of vitamin B or anything else is useless unless a broad approach is made. Finally, does it really matter? Many children brought for anorexia are found to be over weight and gaining steadily. Reassurance of the mother is often the only "treatment" required.

Salty Taste in Mouth

Q.—*An increasing number of patients complain of an unpleasant salty or metallic taste in the mouth, without relation to food, and with no abnormal conditions of teeth, gums, tongue, or accessory sinuses; no signs of hysteria or of perverted taste sensations. Testing the sense of taste in the usual way gives normal results. Is there any possible dental cause?*

A.—Patients who have had recent amalgam fillings occasionally complain of a metallic taste, especially if the filling is in contact with another gold or amalgam filling or gold denture; but this usually passes off after a time. If the abnormal taste is really distressing and can be traced to the new filling, this must be removed and replaced by some non-metallic material. That this complaint is on the increase does not seem to be a general observation. Patients who are receiving injections of the heavy metals sometimes complain, especially when the gums become inflamed.

Ocular Diplopia

Q.—*I find that the subject of ocular diplopia, in particular the diagnosis of the muscle or muscles involved, is not very well done in many of the eye and general medical textbooks. Is there a textbook or monograph you can recommend?*

A.—Diplopia is so wide a subject that any short description must lack sufficient clarity to make the subject really understandable. Double vision may be divided into that which is met with in one eye and that which appears only when both eyes are open. The former is, *inter alia*, found with lens opacities and sometimes during orthoptic training, when both a true and false macula are being used in one eye. Binocular diplopia is of course seen as a normal appearance of objects nearer than or beyond a constant point of fixation of the gaze. This type is called physiological. Artificial diplopia can be produced by digital pressure on one eye, especially in an upward or downward direction or by a prismatic effect—as, for example, when spectacle lenses are badly dispensed. The third type (pathological) is seen in many different kinds of case—e.g., displacement of the eyeball and partial or complete paralysis of one or more of the extraocular muscles. The above is merely a list of some of the causes of diplopia; to extend the list and to embark upon a differential diagnosis of any practical value would entail the writing of a small handbook. The method of diagnosing a paresis of one of the extraocular muscles is confusing to many. A succinct account is given in Bishop Harman's *Aids to Ophthalmology* (Baillière, Tindall and Cox, 5s.); having once seen a practical demonstration, no one should experience any difficulty.

Briefly, the underlying principles are to discover which eye is at fault, and then which muscle of the affected eye is deficient in movement. To find the faulty eye, spectacles with red glass in front of one eye and green or white in front of the other are worn by the patient, who is told to keep his head still and only to follow the movements of a light in front of him with his eyes. An elongated light such as a candle flame should be used. The false image is the one which lies farthest in the direction of greatest diplopia and because of its colour can be traced to the affected eye. If the images were crossed over—i.e., right eye image to patient's left—then the eyes are divergent, and an in-turning muscle is at fault. To determine which muscle is weakened, reference must be made to the diagram found in the textbooks. This diagram may be learnt by heart or by repeated reference.

Ichthyosis

Q.—*A girl of 12 years has a chronic dry scaly skin, worse in winter, when the skin of the legs cracks. Lately she has been put on thyroideum siccum, one 1/10-grain tablet daily, with no improvement so far. What is the usual experience of such treatment in these cases?*

A.—The somewhat brief description in this case suggests a mild form of ichthyosis. This is a chronic dryness of the skin, often a familial disorder, and sometimes associated with asthma and hay-fever. The object of treatment is to replace Nature's deficiency by supplying some oily material which does not become rancid, and for this purpose liquid paraffin is usually well tolerated; it is sometimes an advantage to add a small amount of powdered starch to the liquid paraffin before applying it. The object of the treatment should be to make the skin less harsh and dry, using the remedy as often as is necessary to produce this result. Opinions differ as to the value of thyroid, which in the writer's experience is valueless in this condition.

Methylene Blue for Threadworms

Q.—*I have heard methylene blue described as better than gentian violet for treating threadworms, and less likely to cause vomiting. What dose would be needed for a 4-year-old child?*

A.—Pakenham-Walsh (*Lancet*, Nov. 4, 1944, p. 612) records success in two cases of threadworm infection which he treated with methylene blue, "gr. 3 t.d.s. for a week"; so far these results do not appear to have been confirmed. Chopra and Chandler (*Anthelmintics and their Uses*, 1928, p. 197) state: "Methylene blue in doses of 20 grains, large enough to cause nausea and vomiting, acts only as a feeble anthelmintic." The suggested dose for a child 4 years old is 1/4 to 1 grain t.i.d.

Bursa on Knee

Q.—*A man aged 25 received three years ago a shrapnel wound of his right knee. Shrapnel lodged in the end of the femur was removed at operation within a few hours, and he was left with a knee-joint which functioned normally. A month ago, while playing football, he fell on this knee and suffered great pain. The swelling round the joint was excessive but subsided with two days' rest and local lead and spirit lotion; but he was left with a great amount of fluid in the suprapatellar bursa. After a further week's rest the absorption of the fluid from the bursa appeared to cease. About 35 c.cm. of almost pure blood (which did not clot on standing) was aspirated aseptically, and the knee then appeared normal; but in spite of a crêpe bandage the fluid appeared again within a day. A week later another 25 c.cm. of a similar fluid was aspirated, and again, within a few hours, the bursa had refilled. He gives no history of bleeding into or swelling of any other joint, etc. X-ray examination shows no bony abnormality. What is the most likely cause of this condition, and what lines of treatment could be adopted?*

A.—This is a difficult question to answer without clinical contact with the problem. The fact that this young man was able to play football suggests that the previous shrapnel wound is of no importance in the recent episode, particularly if, as is stated, radiography is negative. An independent intra-articular lesion is probable, such as a cruciate ligament rupture or meniscus tear. The statements that "the knee then appeared normal" and that "x-ray examination shows no bony abnormality" are not convincing unless backed by detailed positive or negative notes relating to sites of tenderness, stability, range of movement, muscular competence and wasting, or, on the other hand, the state of bone densities and outlines, joint interval, soft-tissue shadows, etc.

"Non-specific Urethritis"

Q.—*Cases labelled "non-specific urethritis" occur with increasing frequency. What are the latest views on aetiology, bacteriology, and pathology? A man became infected six months ago after intercourse with the woman he wishes to marry. When he is pronounced cured, what are the possibilities of reinfection should the union take place?*

A.—It is not possible to answer this question fully within the space available. There is a good deal of evidence that non-specific urethritis is not an entity but includes a number of conditions such as chronic gonorrhoea (the gonococcus being difficult or impossible to find) and traumatic, chemical, or bacterial conditions due to such organisms as staphylococci, streptococci, *B. coli*, etc. Infestation with *Trichomonas vaginalis* is thought by some to be a not uncommon cause, and a virus has been suspected but not yet incriminated.

Treatment will depend on the cause: a traumatic or chemical urethritis will clear up if the cause is removed, and an alkaline diuretic is often helpful. Inquiry should be made as to the previous use of injections for prophylactic purposes or of irritating contraceptives by the partner. If masterly inactivity, with or without alkaline diuretics, fails, the "sulpha" drugs may be tried, or even penicillin, on the chance that the infecting organism is a sensitive one. Gentle irrigation with mercury oxycyanide 1:8,000 is often successful in bacterial cases, whilst if *Trichomonas vaginalis* is responsible the urine should be rendered and kept alkaline. If all the above measures fail, a careful urethroscopic examination should be carried out in view of the possibility of a stricture or a Littritis being the cause.

Both "sulpha" drugs and penicillin have cured numerous cases, but by no means all; when they have been successful, chronic gonorrhoea was probably the correct diagnosis. Such therapy is, of course, usually empirical. It is doubtful how far patients with non-specific urethritis are infectious. When it is realized how frequently married women suffer from leucorrhoea and what a menagerie of organisms can be found in the vagina of the average multipara, it is surprising how few married men become infected. It is always wise to examine the partner of the patient, remembering to look for *Trichomonas vaginalis*; but Regulation 33B cannot be invoked, since it applies only to the three official forms of venereal disease—syphilis, gonorrhoea, and soft chancre.

In the case of the man who was infected six months ago by the woman he proposes to marry, it is fairly obvious that he is liable to be reinfected by her unless she is treated. Certainly it would be wise to examine her, because if she infected the man, obviously she herself was infected.

There is no doubt that a mild urethritis, difficult to cure and liable to relapse, has become much more common during the last three or four years than it was previously. A good deal of work has been done on it, but the cause has not yet been definitely identified and treatment is largely empirical in consequence. (See also *Brit. J. vener. Dis.*, 1942, **18**, 106.)

INCOME TAX

Payment to Wife

W. B. asks what is "the highest sum one can pay one's wife (for clerical assistance, etc.) free of income tax from the practice account."

*** The only possible answer to this question is that the wife can be paid as much as her services to the practice are worth—and no more. The effect on taxation depends on the extent to which the wife's earnings as an employee would be taxable. At present the wife is entitled to a maximum allowance of £80 against her earnings, and to the 10% earned income allowance, if the husband is not already receiving the maximum amount (£150) of that allowance.

Eire Resident: English Building Society Interest

M. M. asks: "Is an Eire resident liable to the Eire Government for income tax on dividends received from an English building society?"

*** The only reason why such dividends are not assessed on British residents is that under a special arrangement the building societies make payment to the British Government of sums estimated to be a reasonable composition for the tax which would otherwise be due from depositors, etc. So far as we are aware no such payment is made to the Eire Government and the answer to this question is apparently "Yes."

LETTERS, NOTES, ETC.

Names of Drugs

Dr. **Donald V. Bateman** (Woodford Green, Essex) writes: In "Any Questions?" (Oct. 13, 1945, p. 519) there is a question on "Generalized Sweats," in the course of which the questioner refers to phenobarbitone. In the answer mention is made of the same drug but as represented by the word "luminal" with neither capital initial letter nor inverted commas. It is disappointing to find your correspondent falling into the habit of referring to a proprietary product as though the name were an official pharmacopoeial word. Not so very long ago many candidates in a final examination, asked about nikethamide, were nonplussed by what seemed a mysterious word, when they could have written about "coramine" with familiarity. Our authority for a drug's correct name is the *British Pharmacopoeia*; *not* one particular commercial firm's trade mark for its own preparation of the drug.

*** At the same time we should remember that the discovery of the drug is often made by the commercial firm in the first instance, or rather by its chemists.—Ed., *B.M.J.*

Bell's Palsy

Dr. **Edgar Cyriax** (London, W.1) writes: I have read with great interest the article by Drs. H. P. and Cecily M. Pickerill on the early treatment of Bell's palsy (Oct. 6, p. 457). But I feel I must draw attention to a method of treatment of peripheral facial paralysis which is very little known. Briefly speaking, it consists of manual vibrations applied over the mastoid process to promote absorption of the exudation so often present, and of manual mechanical stimulation of the facial nerve by means of "nerve friction" according to the methods of Henrik Kellgren. This treatment, especially as regards the vibrations, can be started immediately, and the combined manipulations give very good results indeed. A complete technique has been described by me in *International Clinics* (1912, 22s, 1, 40) and *Brit. J. phys. Med.* (1943, **6**, 37).

Liver Extracts

Dr. **H. M. Walker** (London) writes: In "Any Questions?" (Oct. 6, p. 482) an inquiry is made regarding the treatment of aplastic anaemia or essential thrombocytopenia with liver extract. The reply contains some statements which seem to be contrary to all established fact, and in many ways misleading. The statement that "it is a good rule that no patient with a blood disorder should be denied the opportunity of responding to liver therapy" is completely at variance with experience and practice. What effect would liver extract have on myelogenous leukaemia or haemolytic anaemia? Liver extract is specific in macrocytic anaemias, and, although it may have some value in combination with iron in iron-deficiency anaemia, its use in the latter condition is by no means generally accepted. The statement that purified extracts are more reliable than crude, and the conclusion that this is due to greater care in clinical testing, is incorrect. Both purified and crude extracts are reliable, and they are submitted to exactly the same type of test. Finally, the statement that the use of proteolysed liver therapy by mouth is superior to any form of intramuscular therapy is just incorrect. Injection treatment is the method of choice, and is supported by all the authoritative writers on the subject.

Infection from Dead Teeth

Dr. **Sydney Pern** (Ballarat, Victoria) writes: In your issue for May 26 (p. 749) Dr. J. B. Parfitt discusses infection from dead teeth. I cannot say that from twenty-five years' experience I am in agreement with him. I have long ago given up the idea that *x*-ray examination was of any value in deciding infection or otherwise, as on so many occasions where the film proved negative extraction showed gross infection and the patient recovered. I would like to quote from a paper by Dr. Russell Hayden, published in the *Dental Cosmos*, read before the Radiological Society of North America on Dec. 10, 1924. The experiments were carried out in the Department of Medical Research, Deaner Institute, Kansas City. Cultures were made in deep tubes of glucose brain-broth agar. He states: "The changes which from the *x*-ray standpoint are usually considered as indicative of infection are all, in fact, evidence of resistance of the host to the infection. In cases of systemic disease arising from chronic foci the very existence of the systemic lesion is in itself evidence of lack of resistance to the focal lesion. It is logical also to assume that the infected pulpless tooth which shows no evidence of infection is a far greater source of danger than one which does show definite radiographic evidence. . . . Cultures have been made of the apical tissues of 1,307 vital and pulpless teeth and the findings compared with the radiograms. Of 490 pulpless teeth negative in the radiogram 10% showed from 1 to 10 colonies, 44% showed 10 or more, and 24% showed over 100 colonies. Of 425 pulpless teeth with positive radiograms 10% showed from 1 to 10 colonies, 60% had 10 or more colonies, and 44% showed over 100 colonies. The incidence of infection is almost as high in the radiographic negative group as in the radiographic positive group. The absence of radiographic evidence of infection at the apex of a pulpless tooth never excludes the presence of active infection. In many cases the radiographic negative tooth is a far greater source of systemic infection that the radio-positive tooth, since in the former there may be little resistance to the infection." With root infection of dead teeth the general belief is that the infection comes from the tooth itself. In many cases this is not so, as Rosenow has shown that intravenous injections of organisms can and do lodge in the pulp of live teeth and set up foci of infection; thus, however carefully teeth are prepared there is always a possibility of their becoming infected at some future time from food-borne micro-organisms, and so it comes about that any dead tooth is always a source of potential danger. Another fallacy is that because a person is not feeling ill he is therefore not receiving any injury from an infected tooth. Organisms can be poured into the blood stream for years before any particular organ or tissue becomes sensitized to that organism, but that does not say their bodies are receiving no injury; bacterial toxins may be circulating in the blood, causing deterioration of blood vessels and cartilages which eventually results in hyperpiesis and chronic arthritis long before any symptoms are manifest to the individual. One finds that a large proportion of the diseases we are called upon to treat are the result of dental infection from either gingival or root infection. An eye specialist not long ago made the remark that a third of his work resulted from dental infection. If we take the fact that *x*-ray examination is of no value in assessing apical infection and that an individual can be receiving gross pathological damage from bacterial toxins without showing any definite symptoms, we have to ask ourselves the question: Is it worth while carrying a dead tooth when the penalties are so great? Surely the time has come for the dental profession to give us some conclusive evidence as to the usefulness or otherwise of any form of treatment in gingival or apical infections. Personally I cannot say that I have seen any permanent results, which means that the individual is left with a virulent streptococcus entering his blood stream.

Herpes Zoster and Varicella

Dr. **B. H. Symon** (London, S.W.8) writes: On Oct. 16 a middle-aged woman consulted me with regard to a definite patch of herpes zoster round the left side of her waist. The symptoms were characteristic. Two days later she sent for me, having developed an attack of varicella, also with characteristic symptoms and hard palate affected. This would surely imply that the virus of the two diseases is the same.

Correction

In Dr. W. W. Shrubshall's letter (Nov. 10, p. 668) there is a small typing error which, though obvious, needs correction. In the last line "over*h*eating" should of course be "overeating."

BRITISH MEDICAL JOURNAL

LONDON SATURDAY NOVEMBER 24 1945

A SURVEY OF FUNGOUS DISEASES IN GREAT BRITAIN

RESULTS FROM THE FIRST EIGHTEEN MONTHS

BY

J. T. DUNCAN, F.R.C.S.I., L.R.C.P.I.

(Emergency Public Health Laboratory, Winchester; and London School of Hygiene and Tropical Medicine)

The new interest manifested in fungous diseases during the last three decades is in some measure a result, but probably in greater measure the cause, of the recent notable advances made in medical mycology, especially in the United States, some South American States, France, and Italy. The study of medical mycology has been neglected by us, but it should not be thought that fungous diseases are less important in Great Britain and the Colonial Empire than in other countries. At the present time little is known of the nature, the incidence, or the gravity of our indigenous or imported systemic mycoses, and much remains to be learned of our common epiphytic infections. Towards the end of 1943 the Committee for Research in Medical Mycology (Medical Research Council) proposed a survey of fungous diseases in Great Britain, and a tentative scheme to collect data was prepared. Pathologists of the Emergency Pathological Service and members of the Pathological Society of Great Britain and Ireland were invited to submit, for mycological examination and identification, morbid specimens or cultures from known, suspected, or possible mycoses, and at a later date a similar invitation was made to readers of the *British Medical Journal* through an annotation (*B.M.J.*, 1944, 2, 283). The response to these appeals, during the first eighteen months, has been gratifying, and correspondence and specimens were received from 140 pathologists and clinicians—the correspondence bearing evidence of the increasing interest which is being taken in the subject. In all, 1,094 specimens were received, which may be classified as follows: From suspected epiphytic infections, 688; fixed tissues for sectioning, 41; fresh tissues for culture, 42; smears and sections, 130; pus, exudates, and other body fluids, 16; cultures for identification, 62; miscellaneous specimens, including sputum, 115.

As no report of any of the grave systemic mycoses referred to in this paper has yet been published by the doctor concerned, detailed clinical or other descriptions of the cases cannot be given in the following summary.

Mycoses of the Central Nervous System

Torulosis.—Fresh and preserved specimens were received from three cases of torulosis of the central nervous system, in all of which a diagnosis of tuberculosis had been made on the symptoms and clinical signs. In two of these cases torulosis was diagnosed at necropsy, and both showed extensive involvement of the brain and spinal cord and their meninges. In the third case the diagnosis of cerebellar tuberculoma was corrected at operation, and this case is of additional interest because a culture of *Debaryomyces neoformans* (syn. *Torula histolytica*) similar to that isolated from the cerebellar lesion was obtained by nasopharyngeal swabbing, which suggests the possible path of the infection. The cultures from these three cases will be compared with those from earlier English cases and several foreign ones.

Mycotic Meningitis.—Mounted sections were received of the spinal cord and meninges of a case of chronic mycotic spinal meningitis. The causative fungus was present in the greatly thickened pia arachnoid, but in the absence of reproductive forms it could not be identified generically. No culture was available for examination.

Mycotic Cerebral Abscess.—Preserved material was received of a localized abscess of the brain, in the pus of which the mycelium of the causative fungus was present in masses. No reproductive form was found, and in the absence of a culture the generic identity of the fungus could not be determined. The abscess seems to have been secondary to a similar infection in the lung.

Actinomycosis.—Pus from lumbar puncture on a case of cerebrospinal actinomycosis yielded a culture of *Actinomyces bovis* Harz. The meningeal infection seems to have started in the region of the temporal bone, and the disease was rapidly fatal.

Mycoses of the Lung

Pulmonary Moniliasis.—Many specimens of sputum were examined from conditions suspected to be moniliasis of the lung, and from the greater number of these *Candida albicans* (= *Monilia albicans*) was cultivated, but as this pathogenic species is known to vegetate as a saprophyte or a harmless parasite in the throats of healthy persons its mere presence in the sputum is of uncertain diagnostic significance. In one case, however, the *fresh* sputum contained masses of actively vegetating *Candida tropicalis* intimately associated with pulmonary cells: the reported symptoms and physical signs and the *x*-ray picture were consistent with the accepted description of pulmonary moniliasis, and the disease yielded quickly to treatment with potassium iodide. Only a single specimen was available for examination, and it is regrettable that a more complete mycological examination of the case could not be made.

As a precautionary measure against contamination of the sputum by fungi present in the fauces and adjacent cavities, it is a common practice to gargle, wash the mouth, and clean the teeth before expectorating into a sterilized receptacle. This method was used in the controlled examination of the sputum of 32 patients suffering from pulmonary tuberculosis with cavitation. In 68.75% of these patients *Candida albicans* was more or less constantly present in the sputum both before and after mouth-cleansing, and it seems possible that in some of these cases the fungus may have been vegetating saprophytically in the lung cavity; but as bronchoscopic exploration was not feasible in this series of cases the significance of the fungus in the sputum is uncertain. In another group of patients with non-tuberculous cavitation of the lung, on whom bronchoscopic swabbing was allowed, *Candida albicans*, although found in the sputum of some both before and after mouth-cleansing, was never found in the bronchoscopic swabbings. It would seem, therefore, that the method of mouth-cleansing in use is not a safeguard against the contamination of the expectorated matter by fungi vegetating in the mouth and adjacent cavities.

Mould Infections.—The potentially pathogenic mould *Aspergillus fumigatus* was found occasionally in samples of sputum, chiefly from tuberculous patients, but its pathological significance could not be established from examination of the sputum alone. However, in one patient with tuberculous cavitation of the lung on whom observation was kept over a period of four months the fungus was found more or less constantly in the sputum, whether collected before or after mouth-washing. Towards the end of the period, with the shrinkage and ultimate closure of the lung cavity, the fungus gradually disappeared from the sputum. It seems possible that in this case *A. fumigatus* was vegetating in the lung cavity; but probably as a saprophyte, for the patient's recovery was not retarded. A culture identified as an unusually thermophilic strain of *A. fumigatus* was isolated from the sputum of a unique case of apparent acute aspergillosis of the lungs. Although the patient's state was critical, complete recovery was effected by administration of potassium iodide after sulphonamide therapy had failed. Convincing proof of mycosis in such a case is difficult to obtain, but the clinical signs and symptoms, and the fact that the fungus was present in the sputum in clumps visible to the naked eye and the patient's serum contained precipitating antibodies against antigenic extracts of the fungus, provide strong presumptive evidence of aspergillosis. The case was reported by Delikat (1945). Histological evidence of mould infection of the lung is rare, but sections of lung tissue from two cases were received. In the first of these the gross appearance suggested miliary tuberculosis, but the "tubercles" were formed of colonies of a mould surrounded by the kind of tissue reaction seen in localized mycoses. The patient was a diabetic who died from gastric haemorrhage, and the fungal infection was probably a secondary incident on the favourable diabetic soil. The distribution seemed to be haematogenous, but the primary focus was not known. No doubt, if the patient had survived the haemorrhage he might soon have succumbed to the mycosis. In the second case the patient had died from Hodgkin's disease involving the lung, and sections of the lung tissue showed a mould, similar in appearance to that seen in the first case, vegetating on the walls of the bronchi. In neither case, however, could the species of mould be identified with confidence in the absence of culture.

Farmer's Lung.—Correspondence and several specimens relating to this disabling pulmonary disorder, described by Fawcitt (1936a, 1936b), were received from practitioners and pathologists in Yorkshire, Cumberland, Lancashire, Wales, Lincolnshire, and Devonshire. It is clinically and radiologically a fairly well characterized disease, and is commonly believed to be a kind of pulmonary mycosis. Briefly the usual history is that a farmer, after working continuously for a time with *mouldy* hay from which a steam-like cloud of fungus-laden dust arises, develops a short dry cough with little or no expectoration; he may also suffer from general malaise, weakness, and slight fever, but the outstanding feature is distressing dyspnoea provoked by any physical exertion. The dyspnoea is related to inspiration and not, as in asthma, to expiration. Removal from exposure to mouldy hay dust is followed by rapid recovery, which is usually complete and permanent if further exposure is avoided. If, as almost invariably happens, the farmer returns to work with mouldy hay, all the symptoms of the attack are repeated, but relief can still be obtained if the exposure is discontinued. With successive seasonal recurrences the disease tends to progress to chronicity; the cough becomes more productive, the abundant sputum is tenacious and frothy or purulent, and slight haemoptysis may occur; physical weakness is marked, and so great is the dyspnoea, after even slight exertion, that the man becomes incapacitated for work. It is an incapacitating rather than a fatal disease. At this stage the lung may show fibrosis, emphysema, and possibly bronchiectasis, and the *x*-ray picture is usually characteristic. The relation of farmer's lung to inhalation of mouldy hay dust is unquestioned, but the commonly held view that it is a true pulmonary mycosis is based only on the occupational history of the patient and the cultivation of moulds from his sputum.

Several specimens of sputum from cases of supposed farmer's lung were received from different parts of the country, and mould spores were often found present. From one specimen alone six different species of *Aspergillus* were cultivated, as well as other moulds. There is no doubt that the fungal elements in the sputum represent, in the main, recently inhaled matter, and it is significant that fungal conidia are scarce or absent in the sputum of patients who have been removed for even a short time from exposure to hay dust. The rapid clinical improvement brought about by a change from the dust-laden atmosphere does not suggest a progressive mycosis, and, although evidence from post-mortem examination is rarely obtainable—for the disease does not tend to cause early death—it is noteworthy that the single necropsy in Fawcitt's (1936a) series of cases did not reveal any sign of pulmonary mycosis. Stall-fed cattle are exposed in a much greater degree than farm workers to inhalation of mouldy hay dust, and a study of these animals, from which post-mortem lung material can readily be obtained, may shed some light on the pathology of the disease. In this connexion it is noteworthy that veterinary surgeons believe that "broken wind" of horses, a disorder similar to farmer's lung in its symptomatology, is caused by feeding on mouldy hay, and it can be prevented if the hay is wetted sufficiently to prevent the dust from rising and being inhaled.

Undoubtedly the fungus is an essential factor in the aetiology of farmer's lung, but its role has not been determined:—(*a*) Does it cause a true pulmonary mycosis? (*b*) Does it behave as an allergen? (*c*) Does it produce, in its growth on the hay, some noxious substance which causes the symptoms and pathological changes? (*d*) Does it, by breaking down the hay fibre, produce a sufficiently fine vegetable dust to cause, by inhalation, a disorder analogous to the byssinosis of cotton-mill workers? The suggestion conveyed in the last question seems to be the most plausible, but there is need for research on this disease.

Actinomycosis of the Lung.—The anaerobic species *Actinomyces bovis* was cultivated from the sputum in two cases. In one of these the lesion appeared to be confined to the lung, but in the other case the lung infection, complicated by empyema, was part of a generalized disease which proved rapidly fatal.

Generalized and Other Mycoses

Sporotrichosis.—A case of the localized, ulcero-gummatous type of sporotrichosis affecting the tissues about the left knee-joint, with partial ankylosis of the joint and some rarefaction of the lower end of the femur, was reported from East Anglia. The disease was of eight years' duration, and *Sporotrichum schenckii* was isolated from the specimen of tissue submitted. Another case, also in East Anglia, was diagnosed as generalized sporotrichosis, but material was not received for examination.

Histoplasmosis.—A unique case of histoplasmosis in which the lesions, apparently confined to the skin, simulated annular lupus was identified histologically and by culture. The *Histoplasma* isolated may prove to be a hitherto undescribed species. Recent observations by American mycologists indicate that some of the grave systemic mycoses formerly thought to be relatively rare but essentially fatal may represent only the terminal stages of an unfavourable development in a much more widespread, milder, and unrecognized disease. It seems possible that the apparent sporadic incidence of histoplasmosis may be explainable by some such occurrence; in fact, Palmer (1945), from the results of mass radiography observations combined with the histoplasmin dermal test, has put forward the hypothesis that a non-fatal unrecognized form of histoplasmosis may be common in certain areas in the United States. A fatal case of histoplasmosis in England was identified before this survey was inaugurated.

Blastomycosis.—Stained sections were received of a lesion on the forearm, excised at biopsy, which presented the character and the parasite of blastomycosis of the American type (Gilchrist's disease). The patient, an airman, had contracted the infection abroad.

Torulosis.—From a case of disseminated torulosis with multiple subcutaneous abscesses *Debaryomyces neoformans* was isolated. No history was obtainable, and the patient was soon lost to sight.

Moniliasis.—In addition to the pulmonary conditions already discussed, *Candida albicans* was isolated frequently and *C. tropicalis* once from cases of dermal moniliasis affecting the feet, hands, finger-nails, groin, axilla, and perineum, and from the mucous membranes of the mouth, vagina, and bladder. Of special interest was a case of chronic glossitis with involvement of the lips, of 21 years' duration, in a naval seaman aged 25. The ulcerating and fibrosing lesions, in which *C. albicans* was present in great masses, had caused much deformity.

of the mouth and tongue. The same species of *Candida* was isolated from recurrent intertriginous lesions on the patient's feet, groins, and axillae.

Cultures were received of *Candida albicans* from three cases of acute mycotic otitis. The mycosis seems to have been secondary to a staphylococcal otitis media which yielded to local application of penicillin, leaving the hitherto dormant *Candida* to dominate the field. That the mere removal of the staphylococcus may have enabled the fungus to spread and cause an acute mycosis seems possible, but it is noteworthy that Keeney *et al.* (1944) have observed that some fungi which are resistant to penicillin may be stimulated to greater activity by this antibiotic.

Tissue sections were received in connexion with two cases of apparent generalized fatal moniliasis from which *Candida albicans* had been isolated. The clinical details are not yet available.

Actinomycosis.—In addition to the three cases, already mentioned, of actinomycosis of the central nervous system and the lung, caused by *Actinomyces bovis*, this anaerobic species was also isolated from three other cases of actinomycosis. A preliminary study was made of six cultures of aerobic types of actinomycetes: from mycetoma of the hand, apparently contracted in India 30 years previously; from actinomycosis of the appendix; from chronic otitis externa contracted in North Africa; from an abscess of the neck following teeth extraction; an acid-fast species from multiple abscesses contracted in India; and another acid-fast species from a deep wound in the lumbar region contracted in North Africa. Correspondence in connexion with these cases confirms the value of penicillin in the treatment of actinomycosis caused by the aerobic as well as that caused by the anaerobic species of *Actinomyces*, and it is to be hoped that some, at least, of these cases will be published by the doctors concerned. In the meantime the further mycological study of the cultures awaits a favourable opportunity.

Miscellaneous Mycoses.—There were two cases of otomycosis or "tropical ear" caused, in England, by *Aspergillus flavus.* Scrapings were received from two cases of "hairy tongue," but the only fungi isolated from them were yeasts of the genus *Saccharomyces*, which may be regarded as contaminants. There is no evidence that hairy tongue is in fact a mycosis. Another example of a doubtful mycosis was a case of chronic sinus of the neck communicating with a deep-seated mass from which ichorous pus was discharged intermittently over a period of eight years, the sinus closing in the intervals between evacuations. Apparently no bacterial cause had been found, and the possibility of epithelial cyst was considered. A specimen of the necrotic pus received for examination contained masses of fungal mycelium, from which a pure culture of a species of *Cephalosporium* was isolated. The relation of this fungus to the lesion is uncertain; it may have been the primary cause or merely a secondary invader which succeeded in establishing a parasitic foothold. No further information or specimens were obtainable.

Idiopathic Lymphadenopathy.—A series of lymphatic glands from cases of possible non-pulmonary tuberculosis was examined mycologically, but no pathogenic fungus was found. Although acid-fast bacilli were not discovered by microscopy in any of the glands, there is little reason to doubt that they were tuberculous, and, in fact, a few were found to be so by inoculation into guinea-pigs.

Mycoses of the Lower Animals.—In addition to epiphytic infections, the naturally acquired deep mycoses of the lower animals, especially rodents, may be important in connexion with fungous diseases of man. Nearly all the grave systemic mycoses have been found in domesticated animals, but none of these animals can be regarded as a reservoir of the infection. On the other hand, desert rodents are known to be the natural reservoir of coccidioidomycosis, and rodents have been suspected in connexion with histoplasmosis. Rats and mice are susceptible to artificially induced infection by many pathogenic fungi. It was hoped, therefore, that material from wild rodents would have been obtained for examination, but none has been forthcoming up to the present time. Two pathologists sent sections of tissue which showed mycoses of the kidney in laboratory rabbits, but in the absence of cultures the genera of the infecting moulds could not be determined. Many specimens were received of aspergillosis of birds in captivity, from all of which *Aspergillus fumigatus* was isolated. This ubiquitous fungus invades the air system and lungs and frequently the solid organs of birds in captivity, but the disease is almost unknown in birds in the wild state. The fungus is commonly present on grains and seeds, but diving birds are affected as well as seed-eaters, and it seems probable that the infecting form of the fungus is the mycelial growth vegetating in stale drinking or other water, which gains entry through the nostrils.

Ringworm Infections

Specimens of materials from ringworm disease of man were received from places as remote as Aberdeen and Northern Ireland, but the greater numbers were from the southern and south-western counties, the London area, and East Anglia. Isolations of 490 cultures of dermatophytes were made, and of these isolates 216 were species usually parasitic on the lower animals; until shortly before the end of the eighteen-months period, however, the total number of "animal" kinds of ringworm fungi isolated had exceeded that of the peculiarly "human" kinds. The species and their respective numbers were as follows: *Microsporum audouini*, 200; *M. felineum*, 98; *M. lanosum*, 58: *Trichophyton tonsurans*, 4; *T. sulphureum*, 6; *T. acuminatum*, 1; *T. rubrum*, 17; *T. discoides*, 15; *T. asteroides*, 24; *T. persicolor*, 2; *Trichophyton* with downy culture (like the "niveum" group of Sabouraud, but probably a pleomorphic variant of *T. asteroides*), 16; *T. rosaceum*, 2; *Epidermophyton floccosum*, 33; *Achorion schönleinii*, 13; and *A. quinckeanum*, 1.

The Microsporons.—*Microsporum audouini* was the most widely distributed fungus causing tinea capitis, and it was the species responsible for epidemics of ringworm in schools and other institutions for the young. The total number of isolates of this species was swollen by the numbers of specimens received from single outbreaks. *M. audouini* seems to be the predominant species causing tinea capitis in the Midlands and the North; while the cat and dog types, *M. felineum and M. lanosum* (now regarded as a single species), were common on school-children in the southern counties and in the London area. In London *M. audouini* and *M. felineum* were found in approximately equal numbers. In an area of Devonshire between Exeter and the coast *M. felineum* predominated in 11 towns or villages, apparently to the exclusion of other microsporons, and the species was also found widely distributed in other parts of Devon, Dorset, and parts of Hampshire. In Portsmouth, where, despite the evacuation of part of the child population, there is statistical evidence of a striking increase in the number of cases of ringworm during wartime, the fungus concerned in the indigenous infections is *Microsporum lanosum*; other species isolated have always been traced to sources of infection outside the borough area. In Lincoln a series of sporadic infections by *M. felineum* occurred over a period of a few months, and, although the same peculiar strain of *M. felineum* was identified in all the cases, there was in no instance a history suggesting infection from another child; presumably all had been infected directly from an animal source. *M. lanosum* and *M. felineum* are transmitted chiefly from child to child, but it seems probable that frequent renewals from the animal reservoir of the infection are necessary for the propagation of this kind of ringworm among children. How long this disease can be transmitted as a child-to-child infection without renewal from the animal reservoir was not determined in the present survey, but among the Portsmouth cases Dr. T. E. Roberts, the school medical officer, obtained in about one-fourth of the *M. lanosum* infections a history of possible contact with a dog or cat presumed to be suffering from ringworm; and in a group of *M. lanosum* infections originating from a puppy in Cardiff Dr. B. A. Thomas noticed that the skin lesions on children infected directly from the animal were more severe than those resulting from the first subsequent child-to-child transmission; which might suggest an early attenuation of the fungus. Some time later Dr. Thomas traced second and third child-to-child transmissions in this series.

Lesions of the scalp caused by the animal microsporons were, on the whole, more acute and showed a greater epidermal reaction than those caused by *M. audouini*, but inflammatory reaction was rare, and only one, rather doubtful, kerion caused by *M. felineum* was reported. Infection of the glabrous skin by the animal types occurred, with or without associated tinea capitis, and, especially in the case of *M. lanosum*, the skin lesions were often inflammatory or crusted. *M. audouini*, on the other hand, usually caused only a simple pilary infection with little if any epidermal reaction and no associated lesion of the glabrous skin; but occasionally a scaly or very mild inflammatory condition of the scalp was reported, and in school epidemics some of the children showed transient circinate lesions on the face or neck and rarely on the trunk. In only one such case, however, was material from the body lesion available for examination and confirmation of the clinical diagnosis. It is therefore not always possible, except in the presence of severe skin lesions, to distinguish the human from the animal types of microsporosis by clinical inspection alone.

Tinea capitis caused by the animal microsporons usually yields readily to treatment with fungicidal ointments, which provoke a local inflammatory reaction, and it is not often necessary to have recourse to *x*-ray epilation. *M. audouini* infections, on the other hand, usually require *x*-ray treatment.

Strain peculiarities were shown in cultures of some species, especially *M. felineum* and *M. audouini*, and were useful in tracing the distribution of an infection. Two cultures of *M. felineum*, from brothers, formed slowly developing glabrous colonies resembling those of *Microsporum ferrugineum*, but in later subcultures the organs characteristic of *M. felineum* were found, albeit in an imperfect form.

The existence, in certain areas, of a relatively large amount of tinea capitis caused by microsporons of the animal type tends to simplify treatment but introduces new problems in epidemiology and control.

The Endothrix (Human) Trichophytons.—Trichophyton sabouraudi (= *T. acuminatum*) was found once only, on chronic onychia of the finger-nails of a hospital nurse who had contracted the infection in childhood. *T. tonsurans* (= *T. crateriforme*) was isolated from three cases of tinea capitis and one case of tinea circinata without scalp lesions. *T. sulphureum* was isolated from six cases in a nursery outbreak of tinea capitis with associated tinea circinata.

The Small-spore and Large-spore Ectothrix (Animal) Trichophytons.—Trichophyton asteroides (= *T. mentagrophytes*, *T. gypseum asteroides*, etc.) was isolated from lesions on the glabrous skin, from tinea capitis, and from "athlete's foot." It was found on adults, on children, and even on babies. The lesion on the glabrous skin was usually a well-defined raised plaque or circle; profuse scaliness and some vesiculation were frequently reported, but, except in one case, no marked inflammation or suppuration. The scalp infection was sometimes mistaken for microsporosis, but the skin of the scalp was more often affected than the hair. In one case there was a double infection in which *T. asteroides* attacked the scalp epidermis and *M. felineum* the hair, and there was a single case of true kerion. In five cases the hair was attacked, usually with involvement of the scalp epidermis. In other cases the lesion the chest, forearms, and shoulder (1 each), the thigh (2), was situated on the scalp epidermis alone (1), the hand (2), the knee (3), the finger-nails (1), in the condition of athlete's foot (4), and in a situation not stated (3).

The suspected animal sources of the infection were horses, cats, dogs, and rodents (white mice), but materials from the suspected animals were not obtained for examination. In other cases the infection was attributed to handling hides, rubbing against a farm gate-post, and falling in a farmyard; in the last case the ringworm developed on an abrasion of the knee caused by the fall.

Trichophyton persicolor was isolated from sycosis on a farm worker and from lesions on the fingers of a farmer's young daughter. *Trichophyton* sp. with downy culture, which is probably a pleomorphic variant of *T. asteroides* and not the "niveum" type of Sabouraud, was isolated from 16 cases, including seven cases of athlete's foot. The character and distribution of the lesions and the histories given were similar to those of the *T. asteroides* infections.

Trichophyton discoides, a common cause of cattle ringworm, was found on farm workers and children, usually "evacuees," living on or visiting farms. In four cases it caused a simple ectothrix-megaspore hair lesion, sometimes associated with tinea circinata, apparently without inflammatory reaction, but there were five cases with severe kerion. In four cases there were only simple scaly lesions of the skin without inflammation, but in two others the skin lesions showed a marked inflammatory reaction. In all cases a history was obtained, directly or by inquiry, of contact with infected calves.

Favus.—Achorion schönleinii was isolated from 13 cases of favus, 8 of which seem to have been clinically atypical. In three—a woman aged 32 and her two young children—the diagnosis of microsporosis had been made because of the greenish fluorescence given with Wood's lamp—an example of the danger of basing the diagnosis on the result of "lamping" alone. The cases of favus had occurred in Sussex, Caernarvonshire, Cambridge, and Aberdeen, and in all except one instance more than one member of a family was affected.

Athlete's Foot.—Tinea pedis and the associated lesions on other parts were investigated in civilian and military patients, and 62 isolations of dermatophytes were made, of which 33 were *Epidermophyton floccosum*, 15 *Trichophyton rubrum*, 5 *T. asteroides*, 2 *T. rosaceum*, and 7 *Trichophyton* sp. with downy culture—probably a pleomorphic variant of *T. asteroides*. On the whole, *T. asteroides* seemed to be associated with the more severe kinds of lesion, and *T. rubrum* infections were the most resistant to treatment. Athlete's foot is of special importance in naval and military practice and in the coal-mining industry, and it merits a fuller investigation in Great Britain. The work on this group of infections will be made the subject of a separate report.

Conclusion

The number of serious systemic mycoses reported may appear small, but it must be admitted that the most promising field for such material has not yet been explored. Of the specimens from grave fungous diseases, 66% were received from one general hospital, and there is no reason to assume that mycoses gravitate to that hospital. It is significant, however, that the pathologist concerned is deeply interested in medical mycology, and no fungous disease escapes his attention. If careful and constant watch were kept for possible fungous diseases in all hospitals it is probable that a considerable number would be found; for mycoses, because of their clinical resemblance to tuberculosis and other infective granulomata, tend to elude diagnosis unless sought for specially. In assessing the results of this survey up to its present stage, it should be understood that under the existing emergency conditions all the examinations and the considerable volume of correspondence devolved, as a part-time duty, on one person, which restricted the scope of the work; but the results obtained indicate that fungous diseases, both indigenous and imported, are not less important in Great Britain than in other countries, and they present a field for further investigation and research.

[The work of mycological examination hitherto carried on at Winchester has been transferred to the Laboratory for Medical Mycology at the London School of Hygiene and Tropical Medicine.]
